SIXTH EDITION

PRINCIPLES AND PRACTICE OF GYNECOLOGIC ONCOLOGY

EDITED BY

Richard R. Barakat, MD, FACOG, FACS

Chief, Gynecology Service, Department of Surgery
Ronald O. Perelman Chair in Gynecologic Surgery
Vice Chairman, Clinical Activities, Department of Surgery
Memorial Sloan-Kettering Cancer Center
New York, New York

Andrew Berchuck, MD

Director, Division of Gynecologic Oncology
Department of Obstetrics and Gynecology
Director, Gynecologic Cancer Program
Duke Cancer Institute
Duke University Medical Center
Durham, North Carolina

Maurie Markman, MD

Senior Vice President for Clinical Affairs
National Director of Medical Oncology
Cancer Treatment Centers of America
Philadelphia, Pennsylvania

Marcus E. Randall, MD, FACR, FASTRO

Professor and Chair, Department of Radiation Medicine
Markey Foundation Endowed Chair
University of Kentucky
Chief, Ambulatory Services, UK HealthCare
Lexington, Kentucky

DISCLAIMER

Care has been taken to confirm the accuracy of the information present and to describe generally accepted practices. However, the authors, editors, and publisher are not responsible for errors or omissions or for any consequences from application of the information in this book and make no warranty, expressed or implied, with respect to the currency, completeness, or accuracy of the contents of the publication. Application of this information in a particular situation remains the professional responsibility of the practitioner; UnitedVRG: the clinical treatments described and recommended may not be considered absolute and universal recommendations.

The authors, editors, and publisher have exerted every effort to ensure that drug selection and dosage set forth in this text are in accordance with the current recommendations and practice at the time of publication. However, in view of ongoing research, changes in government regulations, and the constant flow of information relating to drug therapy and drug reactions, the reader is urged to check the package insert for each drug for any change in indications and dosage and for added warnings and precautions. This is particularly important when the recommended agent is a new or infrequently employed drug.

Some drugs and medical devices presented in this publication have Food and Drug Administration (FDA) clearance for limited use in restricted research settings. It is the responsibility of the health care provider to ascertain the FDA status of each drug or device planned for use in their clinical practice.

To purchase additional copies of this book, call our customer service department at (800)638-3030 or fax orders to (301) 223-2320. International customers should call (301) 223-2300.

Visit Lippincott Williams & Wilkins on the Internet: <http://www.lww.com>. Lippincott Williams & Wilkins customer service representatives are available from 8:30 am to 6:00 pm, EST.

DEDICATION

This book is dedicated to our families—Catherine Barakat and children Joanna, Richard Jr., and Christian Barakat; Brabham Morgan Randall and children Ken, Morgan, and Marycobb Randall; Tomes Markman and children Margaret, Jonathan, Timothy, and Elisabeth Markman; and Amy Berchuck and children Samuel, Jacob, and Benjamin Berchuck. Their patience, good humor, encouragement, and love have inspired us throughout our careers. In this regard, they have each made significant contributions to this book.

PREFACE

The landscape of cancer care is changing rapidly and dramatically, with truly exciting developments in our understanding of cancer biology and the resulting explosion in translational research at the fore. In their preface to the third edition of *Principles and Practice of Gynecologic Oncology*, published in 2000, our predecessors, the founding editors of the PPGO textbook, William J. Hoskins, MD, Carlos A. Perez, MD, and Robert C. Young, MD, anticipated the further growth of multidisciplinary therapy for the treatment of gynecologic cancers, and predicted that “over the next decade it will involve the active partnership of the laboratory scientist.” Now, 13 years later, as we publish the sixth edition of PPGO, multidisciplinary approaches are at the heart of cancer care, multimodal strategies offer improved clinical outcomes in a wide variety of settings and new possibilities in patient quality of life, and targeted therapies now enable the development of truly innovative approaches to individualized treatment.

For the current, sixth edition of PPGO, we have sought to create a text reflective of the changes in the field of gynecologic oncology, and, in so doing, to continue to build on the important contribution to the medical literature of the textbook’s founding editors. To do this most effectively, we have brought on as editor Dr. Andrew Berchuck, Chief of Gynecologic Oncology and Director of Gynecologic Cancer Research at the Duke University Cancer Institute, a practicing oncologist and distinguished researcher who has made significant contributions to the understanding of the molecular pathogenesis of ovarian and endometrial cancer. We are pleased to be able to incorporate his expertise and thoughtful editorial contributions in the current edition.

This textbook has been designed for specialists who care for women afflicted with gynecologic cancer, including surgeons, medical oncologists, radiation oncologists, pathologists, and nurses. It will also serve as a valuable resource for residents and fellows in training for a career in cancer care. As in past editions, we are certain that this new edition contains the most up-to-date information available about the treatment of gynecologic cancers. Returning readers will see changes within—including an attractive and effective new four-color layout—as well as much that is familiar. The textbook’s first section is now “Etiology, Prevention, and Molecular Biology” and includes new chapters on “Molecular Pathogenesis of Gynecologic Cancers” and “Hereditary Gynecologic Cancers”; Section II, now “Diagnostic and Therapeutic Modalities,” features new chapters on “Minimally Invasive Surgery,” “Diagnostic Imaging,” and “Comparative Effectiveness Research in Gynecologic Oncology.” In Section III, “Disease Sites,” we remain committed to the multidisciplinary theme of the textbook, with chapters authored by teams consisting of a surgeon, a medical oncologist, a radiation oncologist, and a pathologist. The textbook’s final section, “Special Management Topics,” focuses on all of the auxiliary concerns so important in the care of all cancer patients, tailored for the GYN oncology setting. As in previous editions, we have rotated approximately 30% of the authors, and all chapters have been either completely rewritten or extensively updated, including the chapters on the three major diseases—ovarian, uterine, and cervical cancer.

With this new edition we are very pleased to be able to offer readers a dynamic online full-color companion to the printed textbook. Viewable through a browser or as a download to your tablet or smartphone, this unique digital version offers the textbook content in a searchable, interactive format with ongoing updates that reflect new developments in the field. Additionally, the entire text plus up to date content has been incorporated into LWWOncology.com, a comprehensive database of the most authoritative content in oncology today, available to individuals and institutions. Readers can now use the digital version of the book in the context of clinic and conferences, and as an authoritative source of knowledge available in real time.

Finally, we wish to thank the readers for their ongoing support, and we look forward to their feedback on the current edition. We will continue to strive to improve the content and quality of this comprehensive textbook, and we hope that *Principles and Practice of Gynecologic Oncology, Sixth Edition* will contribute to the knowledge and wisdom of all those entrusted with the care of women afflicted with gynecologic cancer.

ACKNOWLEDGMENTS

The editors acknowledge the contributions of numerous individuals without whom this book would not have been possible. The talented staff of the publisher, Lippincott Williams & Wilkins, especially Jonathan Pine, Senior Executive Editor; and Emilie Moyer, Senior Product Manager, provided invaluable encouragement, direction, and guidance during the creative process and in technical execution. Shailaja Subramanian provided outstanding production services. From the Gynecology & Breast Services Academic Office, Department of Surgery, Memorial Sloan-Kettering Cancer Center (MSKCC), we acknowledge the invaluable contributions of editors Jennifer Grady and Alexandra MacDonald. Their attention to detail, patience, and communication skills were of the utmost importance throughout the publication process. MSKCC Department of Surgery editors Carol Hoidra, George Monemvasitis, David Sewell, and Shan-san Wu contributed their skills and expertise during the proofreading process. Our appreciation for all their efforts cannot be adequately expressed, but we hope they know how much we value their contributions.

SECTION I

ETIOLOGY, PREVENTION, AND MOLECULAR BIOLOGY

CHAPTER

1

Epidemiology of Gynecologic Cancers

LOUISE A. BRINTON ■ VIKRANT V. SAHASRABUDDHE ■ BRITTON TRABERT

Disease-oriented texts often include a chapter on epidemiology or etiology, which is considered perfunctory if the book is used by therapists whose daily practice is rarely influenced by these considerations. This is not the case for physicians who treat patients with gynecologic cancers, because these clinicians have frequent opportunities to interpret epidemiologic findings and make observations of etiologic importance. Moreover, public health measures based on epidemiologic findings influence gynecologic practice perhaps more than any other clinical discipline. In particular, epidemiologic data are critical for the prevention and early diagnosis of cervical and uterine cancers.

From the observation 150 years ago of the rarity of cervical cancer in nuns to the most recent follow-up studies of type-specific human papillomavirus infection, determining the cause, natural history, and prevention of this disease has focused on sexual practices and suspect infectious agents. Screening interventions based on natural history studies have fundamentally altered the usual presentation of this disease, and as more information about preceding infectious processes becomes available, even more radical changes in presentation and management are likely.

The probable estrogenic cause of endometrial cancer was proposed by etiologically oriented gynecologists decades before its demonstration by epidemiologists. Unfortunately, this did not prevent the largest epidemic of iatrogenic cancer in recorded history (i.e., endometrial cancer caused by unopposed estrogen therapy). The resurgent interest in menopausal hormone therapy, effects of progestins added to this regimen, and associated risk-benefit questions are certain to link the epidemiologist and the gynecologist for the foreseeable future. The iatrogenic chemoprevention of endometrial and ovarian cancers through oral contraception has similarly thrust the two disciplines together around issues ranging from basic biology to risk-benefit assessments.

The rich tradition of the mingling of epidemiology and gynecologic oncology has led to better opportunities for prevention, screening, and gaining insights into basic mechanisms of disease than for any other subspecialty concerned with cancer. This chapter is written with the aim of clarifying how epidemiology is an integral part of the effort to reduce the morbidity and mortality from gynecologic cancers in women.

In this chapter, we review results from a number of epidemiologic investigations, mainly observational studies, including cohort and case-control studies. There have been a number

of large cohort studies focused on women, such as the Nurses' Health Study and the Million Women Study, and these have provided much useful information regarding etiologic factors for gynecologic cancers. However, these investigations, which collect baseline information and then follow subjects forward in time to capture information on incident cancers, are often limited in terms of the exposure information that is captured. They also are not usually useful for exploring risk factors for rare malignancies, and thus, we also depend on results from case-control investigations to clarify risks. Although these studies more often raise concerns regarding the possible role of selection and recall biases because of the retrospective nature of the information gathered from women with certain cancers and nondiseased comparison subjects, they oftentimes collect more exposure information that can be informative in terms of controlling for the influence of confounding factors and assessing interactions between risk factors (effect modification). The issue of control for confounding (i.e., disentangling effects of correlated variables in terms of identifying the independence of effects) is an important issue for both case-control and cohort studies.

In the studies reviewed below, various measures of risk are discussed, including relative risks (RR) from cohort studies and odds ratios (OR) from case-control studies. The RR from a cohort study represents the incidence of disease in women exposed to a factor compared to the incidence in unexposed women. The OR from a case-control study is an approximation of the RR determined by comparing the odds of developing the disease based on an exposure compared to the odds based on lack of the exposure. There are uncertainties with both these measures, which are influenced by the prevalence of the exposure, the incidence of the disease, the numbers of cases included in a study, and the amount of random variability inherent in the data-collection process. In an attempt to quantify the random error that underlies the risk estimate, the RRs or ORs are usually accompanied by derived 95% confidence intervals (CI). The 95% CI means that if the data collection and analysis were replicated an infinite number of times, the CI would include the true risk estimate 95% of the time. Significantly elevated or decreased risks are indicated, respectively, if the lower confidence limit exceeds 1.0 or the upper confidence limit is less than 1.0. Thus significance levels are comparable, although not precisely equivalent, to $p < 0.05$, which is commonly used as a standard level of acceptance of a risk that is interpreted as importantly elevated or decreased.

UTERINE CORPUS CANCER

Demographic Patterns

Cancer of the uterine corpus (hereafter referred to as uterine cancer) is the most common invasive gynecologic cancer and the fourth most frequently diagnosed cancer among U.S. women today. One in 40 U.S. women will develop uterine cancer during her lifetime, and it is estimated that there were approximately 46,470 diagnoses during 2011 (1). The average annual age-adjusted (2000 U.S. standard) incidence from the Surveillance, Epidemiology and End Results (SEER) program, a cancer reporting system involving approximately 28% of U.S. residents, was 23.9 per 100,000 women for 2004–2008; the corresponding age-adjusted mortality rate was 4.2 per 100,000 women, reflecting the relatively good prognosis for this cancer (2). The 5-year survival rate is approximately 81.8%. It is estimated that approximately 8,010 women will die from uterine cancer during 2012 (1).

Uterine cancer rates are generally highest in North America and Northern Europe, intermediate in Southern Europe, temperate in South America, and low in Southern and Eastern Asia (including Japan) and in most of Africa (except southern Africa) (3) (Fig. 1.1). The disease is rare before the age of 45 years, but the risk rises sharply among women in their late 40s to middle 60s (Fig. 1.2). The age-adjusted incidence for Whites is approximately twice the incidence for non-Whites (Fig. 1.3). Reasons for the discrepancy remain largely undefined. Within the last several decades in the U.S., a dramatic change in the incidence pattern for uterine cancer has occurred, characterized by a marked increase that peaked around 1975 (4). Considerable evidence has linked this rise and fall with the widespread use of unopposed estrogen therapy in the late 1960s and early 1970s. Mortality rates, albeit considerably lower, have generally mirrored incidence rates (Fig. 1.3).

Reproductive Risk Factors

Nulliparity is a recognized risk factor for uterine cancer. Most studies demonstrate a two- to threefold higher risk for nulliparous women than for parous women. The association of uterine cancer with nulliparity has been suggested to reflect prolonged periods of infertility. The hypothesis that infertility is a risk factor for uterine cancer is supported by studies showing higher risks for married nulliparous women than for unmarried women. Several studies have found that infertile women experience a three- to eightfold increase in risk (5,6). Mechanisms that may mediate the risk associated with infertility include anovulatory menstrual cycles (i.e., prolonged exposure to estrogens without sufficient progesterone), high serum levels of androstenedione (i.e., excess androstenedione is available for conversion to estrone), and the absence of monthly sloughing of the endometrial lining (i.e., residual tissue may become hyperplastic). In addition, nulliparity has been associated with lower levels of serum sex-hormone-binding globulin (SHBG), leading to increased bioavailable estrogen (7).

It has been established for many years that the risk of uterine cancer decreases with increasing parity, especially among premenopausal women (8,9). More recent attention has focused on characteristics of ages at which these births occurred. Several investigators have found decreased risks with either older ages at or shorter intervals since a last birth, and have suggested that this might reflect a protective effect of mechanical clearance of initiated cells (10,11).

An understanding of the effects of infertility on cancer risk must also consider relationships according to different methods of birth control, including oral contraceptives (discussed later in this chapter). However, it is also of interest that a number of investigations have noted reductions in risk among users of intra-uterine devices, as discussed in a recent meta-analysis (12). The mechanisms involved with this apparent protective effect have not been elaborated, although it is possible that the devices may

FIGURE 1.2. Age-specific uterine cancer incidence rates by race, U.S. SEER-17, 2000–2008.

affect risk by causing structural or biochemical changes that alter the sensitivity of the endometrium to circulating hormones.

An additional area of interest is the effect of exposure to fertility drugs, given several studies that have shown that users of ovulation-inducing drugs are at an increased risk of developing uterine cancers (13,14). Although this observation requires replication, it is of interest given the structural similarity of clomiphene and tamoxifen, which has been extensively linked with the occurrence of uterine cancers (discussed in more detail below).

The relationship of risk to breast-feeding remains controversial. Although some studies suggest that prolonged lactation may offer protection (15), this has not been noted in all investigations (11).

Menstrual Risk Factors

Early ages at menarche have generally been related to an elevated risk for uterine cancer in many studies. A recent report from a large multicenter prospective cohort reported a 30% reduction in risk with late age at menarche and an inverse dose-response trend (11). Stronger effects of ages at menarche may prevail for younger women (11). The extent to which these relationships reflect increased exposure to ovarian hormones or other correlates of early menarche (e.g., increased body weight) is unresolved.

Most studies have indicated that age at menopause is directly related to the risk of developing uterine cancer. Approximately 70% of all women diagnosed with uterine cancer are postmenopausal. Most studies support the estimate that there is about

FIGURE 1.3. Uterine cancer incidence and mortality trends among US women, SEER-17, 1973–2008.

a twofold risk associated with natural menopause after the age of 52 years compared to before the age of 49 years (16). It has been hypothesized that the effect of late age at menopause on risk may reflect prolonged exposure of the uterus to estrogen stimulation in the presence of anovulatory (progesterone-deficient) cycles. The interrelationships among menstrual factors, age, and weight are complex, and the biologic mechanisms of these variables operating in the pathogenesis of uterine cancer are subject to substantial speculation.

Exogenous Hormones

Oral Contraceptives

The use of combination oral contraceptives may reduce the risk of uterine cancer by 40% to 60%, and long-term use may decrease the risk further (11,17). One meta-analysis noted that the decreased risk persisted more than 20 years after ceasing use (18). In several studies, the greatest reduction in risk was associated with high-progestin-dose pills, although recent findings indicate that this may be true only among obese women (19).

Menopausal Hormones

It is well established that unopposed estrogens are associated with a 2- to 12-fold elevation in uterine cancer risk (20). In most investigations, the increased risk does not become apparent until the drugs have been used for at least 2 to 3 years, and longer use of estrogens is generally associated with higher risk. The highest RRs have been observed after 10 years of use (up to 20-fold), although it is unclear whether risk increases after 15 years. Most but not all studies have found that cessation of use is associated with a relatively rapid decrease in risk, although a number of studies have found significantly elevated risks to persist 10 or more years after last usage. Although higher doses of estrogen are associated with the greatest elevations in risk, one study showed that even 0.3 mg of unopposed equine estrogen can result in a significant increase in risk (21).

This large body of evidence linking estrogen use to increases in the risk of uterine cancers has led to estrogens being prescribed in conjunction with progestins among women who have not had a hysterectomy. Progesterone has been shown to cause regression of endometrial hyperplasia, the presumed precursor of uterine cancers (22). The large Women's Health Initiative (WHI) clinical trial showed that women assigned to 0.625 mg of conjugated equine estrogen plus 2.5 mg of medroxyprogesterone acetate daily had a lower hazard ratio (0.81, 95% CI: 0.48–1.36) than those assigned to placebo, but this risk was based on relatively small numbers of endometrial cancers and short follow-up (23). Similar observational results derive from the Million Women Study in the United Kingdom, where usage of continuous combined therapy resulted in a relative risk of 0.71 (95% CI: 0.56–0.90) (20).

Although a number of studies indicate that the excess risk of uterine cancer associated with estrogens can be significantly reduced if progestins are given for at least 10 days each month (24,25), some studies have shown that subjects prescribed progestins for less than 10 days per month (sequential users) experience some increase in risk, with only a slight reduction compared to estrogen-only users (26,27). The sharp contrast between the effects of <10 and ≥10 days of progestin use has led to the suggestion that the extent of uterine sloughing or of “terminal” differentiation at the completion of the progestin phase may play a critical role in determining risk. It remains questionable whether 10 days of progestin administration per month is sufficient for complete protection, particularly for long-term users (24). Few studies have had large numbers of long-term sequential users, but there is some evidence that this pattern of usage may result in some persistence of risk (28).

Studies have shown that the effects of hormonal therapy (both unopposed estrogens as well as combination therapy) may vary by user characteristics, most notably by a woman's body mass. A number of studies have shown that the adverse effects of unopposed estrogens were greatest in nonobese women and that the beneficial effects of combined therapy were greatest in obese women (20,28,29).

Most data regarding effects of hormones derive from studies on users of pills. Unresolved is whether the use of estrogen patches, creams, or injections can affect risk; given relationships of risk with even low-dose estrogens, it is plausible that these regimens may confer some increase in risk.

Tamoxifen

A number of clinical trials and one population-based case-control study have demonstrated an increased risk of uterine cancer among tamoxifen-treated breast cancer patients (30,32). This is consistent with tamoxifen's estrogenic effects on the endometrium. Elevated risks have been observed primarily among women receiving high cumulative doses of therapy, usually in

the range of 15 g or greater. The risk for more high-risk endometrial cancer histologies may be especially elevated (33).

Anthropometry and Physical Activity

Obesity

Obesity is a well-recognized risk factor for uterine cancer and may account for up to 25% of cases (34). Very heavy women appear to have exceptionally high risks (29). Although studies have demonstrated significant positive trends of uterine cancer with both weight and various measures of obesity, including BMI (weight / height²), height has not been consistently associated with risk. Obesity appears to affect both premenopausal and postmenopausal uterine cancer.

Although initial studies hypothesized that adolescent and long-standing obesity may be more important than adult weight, recent studies support that contemporary weight and weight gain during adulthood are the most important predictors of uterine cancer risk (29,35). Relationships with obesity may be stronger for postmenopausal disease and among women not exposed to exogenous hormones (29,36).

Recent interest has focused on determining whether the distribution of body fat predicts uterine cancer risk. A number of studies have shown that central obesity may have an effect independent of overall body size (29), although not all studies confirm this relationship.

Physical Activity

Recent investigations have focused on the role of physical activity in the etiology of uterine cancer. A potential relationship is biologically appealing given that physical activity can result in changes in the menstrual cycle, body fat distribution, and levels of endogenous hormones. Accumulating evidence suggests a protective effect of physical activity on uterine cancer risk independent of relationships with body weight. A recent meta-analysis of prospective studies demonstrated a decreased risk of uterine cancer with moderate-to-vigorous physical activity independent of relationships with known potential confounders, namely obesity, menopausal hormone therapy use, and parity (37). Generally, studies that have evaluated occupational and recreational physical activity have reported decreased risks.

Inadequate physical activity has been evaluated as a potential risk factor for uterine cancer; specifically sedentary behavior, often measured as sitting time, has been associated with increased risk of uterine cancer (37,38). It is still not clear, however, from the existing studies if the association is independent of moderate-to-vigorous physical activity or body weight (37). Indirect support for a link between sedentary behavior and uterine cancer risk comes from occupational studies, in which the increased risk among women with sedentary jobs is very clear.

Cigarette Smoking

A reduced risk of uterine cancer among smokers has been reported, with current smokers having approximately half the risk of nonsmokers (39–41). Cigarette smoking has been linked to an earlier age at natural menopause in some populations and to reduced levels of endogenous estrogens. Reduced risks may be more pronounced in parous or obese patients (42).

At present, biologic mechanisms underlying the inverse relationship of smoking to uterine cancer risk remain elusive. Alterations in endogenous hormones or metabolites are likely involved. In one report (43), the inverse association of smoking with uterine cancer risk appeared to be more strongly related to higher serum androstenedione levels than to lower serum estrogen levels, except perhaps among overweight women.

Dietary Factors

Despite the fact that obesity has been consistently related to uterine cancer, the role of dietary factors remains controversial. Geographic differences in disease rates (i.e., high rates in Western and low rates in Eastern societies) suggest that nutrition has a role, especially the high content of animal fat in Western diets. Armstrong and Doll (44) demonstrated a strong correlation between a country's total fat intake and uterine cancer incidence.

Dietary Fat

Although early studies speculated that dietary fat intake (particularly animal fat) might play a role in the etiology of uterine cancers, results from more recent studies have provided inconsistent results (45–47). The Women's Health Initiative Dietary Modification Randomized Control Trial, which evaluated chronic disease risks related to a low-fat diet, revealed no effects on the incidence of uterine cancers (48).

Fruits, Vegetables, and Associated Micronutrients

Some studies suggest a reduction in the risk of uterine cancer related to high intakes of fruits and vegetables (49,50). Various micronutrients have been implicated as responsible for this association, although their independence from each other and from other risk factors has not been fully resolved (51). Further, not all studies support relationships with fruits and vegetables, including several large cohort studies (52,53).

Other Dietary Factors

Given the recognized role of diabetes in the etiology of uterine cancers, a number of studies have assessed risk in relation to carbohydrate intake, glycemic intake and glycemic load, which are known to increase insulin and estrogen levels. There are suggestions that all three factors may relate to risk (54–56), although further studies are needed to sort out their independence from other risk factors, including obesity, diabetes, and physical activity levels. Acrylamides, a probable human carcinogen detected in various heat-treated carbohydrate-rich foods, have recently been linked to possible increases in endometrial cancer risk in several studies (57,58). Several studies have found that consumption of phytoestrogens and omega-3 fatty acids (found in fatty fish) may be protective (59,60).

Alcohol and Caffeine

Although early studies suggested that alcohol consumption might lead to reductions in endometrial cancer risk, the findings may have reflected residual confounding by cigarette smoking. More recent studies suggest either no association or one that is increased modestly (61,62).

A recent meta-analysis of coffee consumption and uterine cancer reported a decreased risk of cancer with one cup of coffee per day or more, with consistent findings across case-control and cohort studies (63). In a meta-analysis of green and black tea, green tea was associated with a decreased risk of uterine cancer, whereas black tea was associated with an increased risk of uterine cancer (64); however, the summary measures were based on a small number of studies and should be considered preliminary.

Medical Conditions

Numerous clinical reports link polycystic ovary syndrome (PCOS) with an increase in the risk of uterine cancer, particularly among younger women; however, it is uncertain whether

this risk is independent of obesity. In a recent systematic review and meta-analysis of case-control studies, women with PCOS were found to be at an almost threefold increased risk of uterine cancer (65). Assessing histories of PCOS is challenging in case-control studies, but it is of interest that uterine cancer has been associated with histories of either hirsutism or acne (5,66), which are conditions often associated with hyperandrogenism.

A number of studies have noted a high risk of uterine cancer among diabetic patients, but questions arise as to the extent to which the association is independent of weight. Some studies (67–69) suggest that the relationship persists when analyses are restricted to nonobese women or are adjusted for weight. However, a stronger relationship between diabetes and endometrial cancer risk among obese women in some studies has prompted interest in the etiologic role of selected metabolic abnormalities, including hyperinsulinemia. Thus, more recent studies have focused on effects of metabolic syndrome, with findings that this may predict risk better than merely a history of diabetes (70,71).

A variety of other diseases, including hypertension, arthritis, thyroid conditions, anemia, and cholecystectomy, have been suggested to predispose to uterine cancers, although without consistent findings (72,73). In a number of studies, positive findings may be partially explained by the correlation of the diseases with other factors. Similar to breast cancer, patients with previous fractures have been found to have a reduced risk of uterine cancer (74), presumably reflecting the association of lowered bone density with altered endogenous hormone levels.

Recent studies have also focused on the effects of use of non-hormonal medications on the risk of developing uterine cancer. Given speculation that inflammatory processes might play an important role in the development of uterine cancers (75), a number of studies have assessed relationships with use of nonsteroidal anti-inflammatory drugs, with inconsistent results (72,76,77).

Host Factors

Although studies have shown that a family history of uterine cancer is a risk factor for the disease, particularly among younger subjects (78), this appears to explain less than 5% of disease occurrence (79). In addition, subjects with a family history of colon cancer are at increased risk (78), an association that is now recognized as reflective of hereditary non-polyposis colorectal cancer (HNPCC), a dominantly inherited syndrome associated with mutations in the DNA mismatch repair genes *MSH2*, *MLH1*, *MSH6*, *PMS1*, *PMS2*, and *TGFBR2*. Lifetime risk of uterine cancer is 44% in HNPCC mutation carriers (*MSH2* and *MLH1*), with a median age at onset in the mid-40s (80).

A number of studies have focused on relationships of uterine cancer risk with common single nucleotide polymorphisms (SNPs), including those involved with obesity (81), hormone biosynthesis, metabolism or receptors (82,83), DNA repair (84), and folate metabolism (85). More recent studies have used more robust genome-wide association approaches to identify genetic variants of importance. In a recent study, a susceptibility locus close to *HNF1B* (rs4430796), which has also been positively associated with prostate cancer risk and inversely with type 2 diabetes, emerged as a significant predictor of endometrial cancer risk (86). Genome-Wide Association Studies (GWAS) have also identified that the SNP rs1202524, near the *CAPN9* gene on chromosome 1q42.2, may host an endometrial cancer susceptibility locus (87).

Environmental and Occupational Risk Factors

Geographic variation in rates of uterine cancer, with high rates in certain industrial areas, has led to the suggestion that

certain environmental agents may affect risk. Given the well-recognized influence of hormones on the disease, there has been particular concern about a potential role for certain endocrine disruptors, including dichlorodiphenyltrichloroethane (DDT). Several studies have addressed this issue by comparing dichlorodiphenyldichloroethylene (DDE) levels (the active metabolite of DDT) in the sera of cases and controls, finding no significant differences (88–90). Several studies have focused on effects of electromagnetic radiation as a risk factor, but findings regarding electric blanket or mattress covers have produced mixed results (91,92).

Data for occupational exposures are limited. Elevated endometrial cancer rates have been found among teachers in California (93) and individuals exposed to animal dust and sedentary work in Finland (94). The extent to which these relationships reflect the influence of social class is unknown.

Etiologic Heterogeneity

In 1983, Bokhman (95) proposed that endometrial cancers could be divided into two broad types: Type I, the predominant form, which has a hormonally driven etiology, and Type II, which is unrelated to typical endometrial cancer risk factors, not associated with endometrial hyperplasia, and generally clinically aggressive. Subsequent clinicopathologic studies led to the view that most Type I cancers correspond histologically to endometrioid adenocarcinomas, whereas Type II cancers encompass most nonendometrioid histologic types, with serous carcinoma representing the prototype (96). Differences in molecular markers according to histology support the notion of at least two broad classes of endometrial carcinoma (97,98).

Although it is generally now embraced that there are at least two main biological types of endometrial cancer (and possibly more), most epidemiologic studies have assessed risk factors for endometrial cancer overall—which essentially represent the risks for the predominant Type I tumors, especially in largely Caucasian populations. Registry data consistently have shown that Type II cancers occur at older ages and more often affect non-White women compared with Type I tumors. Some epidemiologic investigations have found that Type II cancers are less strongly linked to classic Type I risk factors, such as obesity, nulliparity, and hormones (99,100), but these have involved relatively limited numbers of nonendometrioid cancers, incomplete collection of relevant risk factors, and unstandardized pathologic classification of tumors.

Biologic Mechanisms Underlying Risk Factor Associations

Many of the identified risk factors are thought to operate through alterations in various endogenous hormones. The majority of studies have found increased risks associated with higher levels of circulating estrogens among postmenopausal women that persisted after adjustment for the effects of body mass (27,101). Although based on relatively small numbers, several studies have shown that estrogens appear less predictive of premenopausal disease (27,102), suggesting that anovulation or progesterone deficiency might be more influential.

Less well investigated is whether other endogenous hormones are related to uterine cancer risk. Key and Pike (103) suggested that uterine carcinogenesis is dependent on uterine mitosis, which is increased by estrogens and reduced by progesterone, but risk associated with progesterone levels has not been well explored. Several studies have shown positive associations of uterine cancer risk with serum androstenedione and

testosterone levels (27,102,104). It has been hypothesized that this may reflect a role of chronic anovulation and progesterone deficiency in premenopausal women, whereas after menopause, aromatase and local conversion of estrone from androstenedione may be involved (105).

Obesity, which is hypothesized to reflect elevated estrogen levels, seems to represent a key risk factor for both uterine carcinoma and endometrial hyperplasia, but the mechanisms mediating this are unclear. A case-control analysis of serum estrogen levels (102) reported that the risk associated with obesity was not entirely mediated by estrogens, especially among premenopausal women, whereas a cohort study of postmenopausal women showed that elevated serum estrogen levels appeared to account for the majority of the risk associated with obesity (106). A potential role for insulin and insulin-like growth (IGF) factors has been suggested, although studies generally have not found support for a role of either c-peptide (107) or IGF (108) levels.

Conclusions

A unified theory of how risk factors for uterine cancer might operate through one common hormonal pathway has been suggested. Estrogen promotes proliferation in the endometrium, which is opposed by progesterone. Therefore, exposure to estrogen, particularly bioavailable estrogen that is weakly bound or unbound to plasma protein, is viewed as a critical carcinogen. Functional ovarian tumors, PCOS, late menopause, and administration of exogenous estrogens and sequential oral contraceptives and menopausal hormone therapies produce higher levels of estrogen exposure without the antiproliferative effects of progesterone. Obesity could also contribute in a variety of ways (109). Adipose tissue is the primary site for conversion of androstenedione to estrone, which is the primary source for estrogen after menopause. Obesity is associated with higher conversion rates and/or elevated plasma levels of estrogen in postmenopausal women. In addition, obesity is related to lower levels of SHBG and more frequent anovulatory menstrual cycles (i.e., less progesterone). Vegetarianism is associated with lower plasma estrogen levels, presumably on the basis of the relationship of diet composition to estrogen metabolism. The beneficial effects of combination oral contraceptives and continuous progestins added to menopausal hormone therapy presumably operate through the antiestrogenic effects of progesterone. The peculiar age incidence patterns for uterine cancer (i.e., extremely rare under age 45 years, followed by a rapid and progressive rise from ages 45 to 60 years) could also reflect the waning influence of progesterone. Nulliparity, hypertension, diabetes, the absence of smoking, and race may yet be added to the unifying scheme as knowledge of endocrinologic mechanisms in endometrial tissue increases.

Although there are several identified risk factors for uterine cancer (Table 1.1), important gaps in knowledge currently limit a full understanding of the proposed carcinogenic process. We need to understand when in a woman's life obesity matters most and how risk is influenced by weight loss; whether the number of adipocytes, their fat composition, or other factors determine peripheral conversion of androstenedione; and the precise hormonal mechanisms associated with vegetarianism. Perhaps the most important gap is in understanding the basic mechanism of estrogen carcinogenesis. It is unclear whether estrogens are complete carcinogens, classic “promoters” that affect initiated cells, or growth stimulants for abnormal cells or carcinogens that act on vulnerable genetic material. The epidemiologic data are consistent with estrogens acting at a relatively late stage of carcinogenesis, emphasizing the need for further investigations to identify tumor initiators.

Table 1.1 Risk Factors for Uterine Cancer

Factors Influencing Risk	Estimated Relative Risk ^a
Demographic factors	
Older age	2.0–3.0
Residency in North America, Northern Europe	3.0–18.0
Higher levels of education or income	1.5–2.0
White race	2.0
Exposures that increase risk	
Obesity	2.0–5.0
Long-term use of menopausal estrogens	10.0–20.0
Nulliparity	3.0
History of infertility	2.0–3.0
Menstrual irregularities	1.5
Early age at menarche	1.5–2.0
Late age at natural menopause	2.0–3.0
Polycystic ovary disease or estrogen-producing tumors	>5.0
Histories of diabetes, hypertension, gall-bladder disease, or thyroid disease	1.3–3.0
Exposures that decrease risk	
Use of oral contraceptives	0.3–0.5
Moderate-to-vigorous physical activity	0.5–0.8
Cigarette smoking	0.5

^aRelative risks depend on the study and referent group employed.

OVARIAN CANCER

Demographic Patterns

Ovarian cancer accounts for 3% of all incident cancers in U.S. women (1). Approximately 1 in 71 U.S. women will develop ovarian cancer during her lifetime. The average annual age-adjusted incidence for all SEER areas, between 2004 and 2008, was 12.8 per 100,000 women (2). An estimated 22,280 new cases were diagnosed in the U.S. in 2012 (1).

Diagnosis usually occurs at advanced stages; the overall 5-year survival between 2001 and 2007 was only 43.8%. The average annual age-adjusted mortality rate is 8.4 per 100,000 women (2). The estimated 15,500 deaths due to ovarian cancer in 2012 will make it the fifth leading cause of cancer death among U.S. women (1). After rising during the mid-twentieth century, age-adjusted mortality rates have been declining by 1.9% per year since 2002 (1). Incidence rates have also slowly declined over the past 2 decades—ovarian cancer incidence rates decreased by 0.7% per year from 1985 to 2001 and by 1.8% per year from 2001 to 2008 (2). In the U.S., Blacks and Whites have nearly identical mortality rates, but the incidence rates remain higher for White women (110) (Fig. 1.4). Although incidence rate increases with age, at all ages rates are higher for Whites than Blacks (Fig. 1.5).

The highest incidence generally occurs in European, Scandinavian, and North American countries, whereas the lowest rates

FIGURE 1.4. Ovarian cancer incidence and mortality trends among US women, SEER-17, 1973–2008.

occur in African nations and some eastern countries, such as China (3) (Fig. 1.6). Age-standardized rates vary 3.4-fold across countries. Mortality data show a similar but slightly less dramatic pattern (Fig. 1.6). The estimated age-standardized mortality rates are 5.1 in more developed regions and 3.1 in less developed regions (111).

Reproductive Risk Factors

Gravidity is consistently associated with decreased ovarian cancer risk. Compared with nulligravid women, women with a single pregnancy have a relative risk of 0.6 to 0.8. Each additional pregnancy decreases risk another 10% to 15%. The number of full-term births seems most influential, but several studies have also found decreased risks associated with an increasing number of incomplete pregnancies (112). Most studies that adjusted for parity report no residual association with age at first or last birth (113), but some investigators argue that both number of births and timing matter (114,115).

Whether identified reproductive relationships reflect a hazardous role for infertility or merely the protective role of pregnancy is unclear. Studies with higher risks among infertile women support some role for abnormal endocrine factors. In one study (116), sexually active women who were not using contraceptives and had not conceived for 10 or more years were

FIGURE 1.5. Age-specific ovarian cancer incidence rates by race, U.S. SEER-17, 2000–2008.

at a six-fold excess risk compared with other women. Another large study similarly found a high risk associated with nulliparity despite unprotected intercourse, especially in women with long periods of ovulatory experience (117).

Although several early studies showed substantial increases in ovarian cancer risk linked to use of fertility drugs (118,119), subsequent studies have generally not confirmed an association, at least for invasive cancers (120). There are, however, lingering concerns regarding whether fertility medications might increase the risk of borderline ovarian cancers, especially given the results from a recent large Dutch cohort study (121). Whether this reflects a biologic relationship or merely increased medical surveillance among infertility patients is yet to be determined.

A number of studies have found a reduced risk of ovarian cancer associated with breast-feeding, although the association has not always been shown to be independent of parity or to relate to risk in a dose-response relation (122,123). A pooling of two large cohort studies reported inverse trends in risk with extended breast-feeding that were independent of parity effects (124). Notably, each month of breast-feeding decreased the relative risk of ovarian cancer by 2%. A subsequent, large, case-control study in Australia reported consistent risks of ovarian cancer with breast-feeding independent of parity and suggested that the risks of invasive serous tumors were most influenced by breast-feeding (125). Suppression of ovulation and decreased gonadotropin levels were proposed as explanatory of the reduced risks, but further studies are needed to confirm this hypothesis.

Menstrual Factors and Gynecologic Surgery

Numerous studies have noted reduced risks among women who have had a simple hysterectomy or tubal ligation. These patients' risks were 30% to 40% lower than the risks among

FIGURE 1.6. International incidence rates for ovarian cancer (per 100,000 woman-years) age-standardized to the world population, 2008. Source: Ferlay J, Shin JR, Bray F, et al. GLOBOCON 2008 v2.0, Cancer Incidence and Mortality Worldwide: IARC CancerBase No. 10 [Internet]. Lyon, France: International Agency for Research on Cancer; 2010; Available from: <http://globocan.iarc.fr>; accessed on 23 March 2012.

women who had not undergone surgery. A subsequent meta-analysis reported a 37% reduced risk of ovarian cancer with tubal ligation and evidence that the reduced risk persists 10 to 14 years after the procedure (126). This meta-analysis showed the association with tubal ligations to be specific for endometrioid and serous malignancies (126), while another showed stronger reduced risks related to endometrioid than serous cancers (127). It has been suggested that surgery offers an opportunity to remove abnormal-appearing ovaries, but this alone is unlikely to explain the protective effect. Partial devascularization or partial removal of tubes that decreases the risk of tubal carcinogenesis, a precursor to serous ovarian cancer, represents a possible alternative; however, reduced exposure to potential environmental causes of inflammation resulting from tubal ligation or hysterectomy blocking the route of exposure from the outside of the body to the fallopian tube fimbria and ovaries has also been proposed (128).

A number of studies have linked late age at natural menopause with an increased risk of ovarian cancer (113,129,130), although not all studies have confirmed this relationship (131). Most studies have not found earlier ages at menarche to increase risk, but some have reported weak positive associations (116,129,130,132).

Hormonal Risk Factors

Oral Contraceptives

Oral contraceptive use has been consistently associated with a lower risk of ovarian cancer. A pooled analysis of 45 studies reported reduced ovarian cancer risk with long-duration oral contraceptive use (133). The overall estimated protection is approximately 40% for ever use of oral contraceptives and increases to more than 50% with 5 years of use or longer, with the reduction in risk persisting for 30 years beyond last use. The lower-dose formulations, now in use, seem to reduce risk at least as effectively as their higher dose predecessors (134–136). In addition, the androgenicity of the progestins used does not appear to differentiate risks (137).

Menopausal Hormones

Unopposed estrogen menopausal hormone therapy has been consistently associated with an increased risk of ovarian cancer (138). Associations between estrogen plus progestin use and ovarian cancer risk have been less consistent. In the WHI clinical trial, women exposed to estrogen plus progestin therapy had an increased, albeit not significant, risk of ovarian cancer compared to those receiving a placebo (RR 2.42; 95% CI: 0.64–9.12) (23). A meta-analysis of population-based case-control, cohort, and clinical trial data reported an increased risk of ovarian cancer per 5 years of estrogen plus progestin use (139). Further, the recently published Danish Sex Hormone Register study reported increased risk for both sequential and continuous estrogen plus progestin use (140), suggesting that progestins do not mitigate the increased risk associated with estrogen menopausal hormone therapy.

Endogenous Hormones

Recent interest has focused on the role of endogenous hormones in the etiology of ovarian cancer. Although one nested case-control study found higher levels of androgens and lower levels of gonadotropins among cases than among controls (141), the association with androgens was not confirmed in more recent investigations (142–144), whereas the inverse association with FSH was confirmed in an additional nested case-control study

(145). One study, however, found some suggestion that free testosterone might play a role in early onset ovarian cancers (142). Another investigation, which pooled data from three studies, reported null associations with estrogens, androgens, SHBG, IGF-1, and associated binding proteins (IGFBPs) (143,146). Despite these initial null results, there remains interest in further exploring the role of endogenous hormones in the etiology of ovarian cancers, especially given that they may interact with immunologic factors, which have been suggested to play an important role in ovarian carcinogenesis (see below).

Medical Conditions and Medications

Several studies surveyed whether certain medical conditions predispose to ovarian cancer. Diabetes, hypertension, and thyroid diseases seem unrelated to risk (67,147). In line with a number of clinical studies showing simultaneous occurrences of endometriosis and ovarian cancer, a number of epidemiologic studies have found that women with a diagnosis of endometriosis have elevated risks for developing ovarian cancer (148–151). In several of these studies, the relationship was shown to preferentially affect clear cell and endometrioid ovarian cancers (149,150) and more recently also low-grade serous malignancies (151). As reviewed by Ness (152), the two conditions share a number of pathophysiologic processes, including estrogen excesses and progesterone deficits, immunologic responses, and inflammatory reactions. Pelvic inflammatory disease has also been found in several studies to be a possible risk factor for ovarian cancer (128,153,154), supporting the notion of a role for inflammation in ovarian carcinogenesis.

Medications recently surfaced both as potential risk and protective factors. Several studies showed increased risks among users of psychotropic medications, particularly those operating through dopaminergic mechanisms (155). However, subsequent studies that employed cohort designs or improved exposure assessment reported null associations (156–159). Findings also have suggested a reduced risk among women who used anti-inflammatory or other analgesic medications (160–162), and a meta-analysis reported a weak inverse association between acetaminophen use and ovarian cancer risk (163). However, as with the psychotropic medication data, subsequent studies showed, at most, a weak and inconsistent association. Chemoprevention via the use of these medications remains a premature concept.

Anthropometry and Physical Activity

Obesity has recently received increased scrutiny as a possible risk factor. Most individual studies fail to show an association, but pooling projects and meta-analyses are beginning to indicate increased risks associated with higher BMIs (164–166). An increased risk with obesity in premenopausal women was reported in a pooled analysis of 12 cohort studies, but they did not observe an association among postmenopausal women (166). The European Prospective Investigation into Cancer and Nutrition (EPIC), however, reported an excess ovarian cancer risk primarily among postmenopausal women (167). Some investigations have shown stronger relationships restricted to certain subgroups, including those who have never had children (168), nonusers of menopausal estrogens (165,169), women without a family history of ovarian cancer (169), and physically inactive women (170). Further, some studies have suggested that obesity is a risk factor only for certain types of tumors. However, the histologic subgroups identified as being increased among obese women have varied across studies (167,171).

Height has also recently emerged as a risk factor independent of obesity (165,166). Studies have also examined effects of

physical activity levels on ovarian cancer risk, although results are inconclusive, with some studies showing inverse relations, others showing positive associations, and still others noting no association. The most recent meta-analysis reported a 19% risk reduction associated with recreational activity, although the association was not statistically significant when only cohort investigations were considered (164).

Cigarette Smoking

In general, cigarette smoking is not considered a major risk factor for ovarian cancer. However, a number of studies have found evidence that there may be an increased risk of mucinous tumors associated with smoking (172). In a systematic review, smoking was found to lead to a significant doubling in risk for mucinous tumors but not an increased risk for endometrioid or clear cell tumors (173). The risk of mucinous cancers increased with amount smoked but returned to that of never smokers within 20 to 30 years of stopping smoking. Fewer studies have evaluated effects of passive smoking on ovarian cancer risk, with no consensus as to whether this might alter risk or have histologic specificity (174,175).

Dietary Factors

Ecologic studies of dietary factors and ovarian cancer risk led to the hypothesis that high intake of fat, milk, and eggs may be related to an increased risk of ovarian cancer while high intake of fruits and vegetables may be related to a decreased risk (44). However, the majority of the observational studies targeting food classes, lactose and dairy foods, fats, vitamins/nutrients, fiber, fruits, and vegetables, provide conflicting results.

Lactose Consumption

Findings linking higher consumption of yogurt, cottage cheese, and other lactose-rich dairy products with an increased risk of ovarian cancer (176) were viewed with interest given that galactose-related enzymes can influence gonadotropin levels, which are hypothesized to be crucial ovarian cancer risk determinants. The majority of subsequent studies failed to show increases in risk with lactose consumption or galactose metabolism (177;178), although a few studies have provided some support for the hypothesis (179,180). Results from the Nurses' Health Study suggest that further attention may be warranted regarding effects for serous tumors (181).

Fat Intake

The Women's Health Initiative Dietary Modification Randomized Control Trial evaluated the effects of a low-fat dietary pattern on chronic disease incidence, and reported a decreased risk of ovarian cancer associated with the intervention (a 20% reduction in total fat intake) (48). Although some case-control studies have reported higher risks of ovarian cancer associated with intake of fatty foods (e.g., butter and meats) as well as types of fat, the observational data are not entirely consistent. Cohort studies have also been inconsistent, with earlier studies reporting no relationship with dietary fat consumption and recent studies reporting a small, albeit increased, risk with total fat, fat from animal sources, polyunsaturated fats, and trans fat. A meta-analysis of 12 cohort studies found no overall association with fat, cholesterol, or egg intake, but suggested that very high levels of saturated fat intake may increase risk (182). Additional meta-analyses reported no association between red meat and inconsistent results for high intake of processed meat (183,184).

Fruits and Vegetables and Micronutrient Intake

Although some studies have suggested that ovarian cancer risk might be reduced by higher consumption of fruits and vegetables (177,185) or fiber (186,187), while others, including a pooling project of 12 cohort studies, fail to support these relationships (188). Some studies showed inverse associations with particular nutrients, such as vitamins A, C, E, beta-carotene, folate, or methionine (189–192), although results have not been consistent across studies. A meta-analysis evaluating vitamin D and ovarian cancer risk reported no association (193). Further clarification of effects may require evaluating associations according to other risk factors and within histologic subgroups.

Alcohol and Caffeine

A number of studies have examined the effects on ovarian cancer risk related to alcohol consumption. Most have not found any convincing relationships, including a pooled analysis of 10 cohort studies (194).

Caffeine and ovarian cancer risk has been evaluated in studies of coffee consumption, tea consumption, and both combined. Coffee consumption was linked to an elevated risk of ovarian cancer in several early studies and a recent cohort study (195); however, additional studies have not replicated the association (196,197). One study on coffee and tea consumption suggested an inverse association with coffee consumption, but concluded that this was not due to caffeine intake since no relationship was observed with tea consumption (198). A systematic review of tea consumption reported no association with ovarian cancer risk (199); however, a subsequent meta-analysis reported reduced ovarian cancer risk with green tea consumption and no association with black tea consumption (64). Finally, a cohort study reported a modest inverse association of caffeine consumption with ovarian cancer; however, this association was specific to nonhormone users (200). Overall, there are no consistent patterns between caffeine consumption and ovarian cancer; it may be that more detailed information on source of caffeine, frequency, and duration need to be evaluated.

Host Factors

A family history of ovarian cancer is the strongest risk factor identified to date. Which family member was affected is less important than the total number of affected relatives or their age at diagnosis. Women with two or more affected relatives or whose relative was diagnosed before 50 years of age experience the highest risks (201). Approximately 5% to 10% of ovarian cancer patients have a first-degree relative with ovarian cancer (202). Family histories of breast and colon cancer are also associated with increased ovarian cancer risk but slightly less strongly than a family history of ovarian cancer.

Inherited mutations in two autosomal dominant genes—*BRCA1* and *BRCA2*—are strongly linked to familial ovarian cancer (and breast and other cancers) (203). Whereas the lifetime probability of developing ovarian cancer in most women is 2%, the probabilities in women with a family history or women with a *BRCA1/2* mutation are 9.4% (204) and 15% to 40% (205), respectively. Despite these increases, *BRCA1/2* mutations explain less than one third of the elevated risk in women with familial ovarian cancer (201). Lynch syndrome, or hereditary non-polyposis colorectal cancer (HNPCC), is related to mutations in mismatch repair genes and reported to be associated with a 12% lifetime risk of ovarian cancer (206). Disease heterogeneity is influenced by high-penetrance genetic variation, whereby mutations in *BRCA1/2* lead to the development of serous cancers and mutations of DNA mismatch repair genes are

more frequently associated with mucinous and endometrioid tumors (207).

Common genetic variation and ovarian cancer risk in moderate- or low-penetrance susceptibility genes have been evaluated using candidate gene studies of SNPs and through GWAS. Candidate genes/SNPs have generally been selected from biologic pathways based on relevant hypotheses, and several candidate genes have been identified to date, including *PGR*, *TP53*, and *CDKN2A*. GWAS have further identified susceptibility loci for ovarian cancer at 9p22.2, 8q24, 19p13, 2q31, 3q25, and 17q21 (207). Identifying common genetic susceptibility alleles will lead to a greater understanding of disease etiology, potentially leading to the development of preventive approaches targeted toward women who have these genetic variants.

Talc

Like asbestos, over-the-counter talc such as asbestos, is a silicate that has been studied in relation to ovarian cancer risk. The published case-control studies generally report positive associations between ovarian cancer and perineal talc exposure; summary estimates suggest a 30% increase in risk (208,209). However, a lack of consistent statistical significance and inconsistent associations with different patterns of talc use raise questions about the validity of this association.

Environmental and Occupational Risk Factors

Certain occupations came under scrutiny when studies linked hair dyes and triazine herbicides to ovarian cancer (210,211). Record linkage studies in Finland (212), Norway (213), Sweden (214), Canada (215), and the U.S. (93,216) suggested a pattern of increased risks among certain professions (e.g., teachers, health care workers) or with particular occupational exposures (e.g., solvents, asbestos). It was recently concluded in a Monographs Working Group of the International Agency for Research on Cancer (IARC) that asbestos exposure is associated with ovarian cancer; a subsequent meta-analysis of occupational cohorts reported increased ovarian cancer mortality among women occupationally exposed to asbestos (217). Until additional data address the potential for inconsistent or chance findings and the challenge of finding large populations with sufficient data on other potential confounding variables, occupational exposures beyond asbestos will likely not be considered major risk factors for ovarian cancer (218).

Etiologic Heterogeneity

A unified ovarian cancer progression model has not yet been established, and growing evidence demonstrates that subtypes of ovarian carcinomas have different molecular, pathological, and clinical characteristics, suggesting that there may be several distinct disease entities (219). Specifically, ovarian cancer subtypes have been described to molecularly and morphologically resemble cancers of other sites: fallopian tube (serous), endometrium (endometrioid), gastrointestinal tract (mucinous) and unspecified glycogenated epithelium (clear cell) (220).

As previously discussed, some risk factors have been shown to have distinctive effects for certain subtypes of ovarian cancer, but there have been inconsistent findings—most likely reflecting small numbers in the studies of some of the rarer subtypes. Probably one of the more consistent findings is the propensity of endometriosis to predispose to clear cell and endometrioid tumors (149–151), suggesting that a subset of disease does not

arise in the ovary but rather from transplanted endometriotic tissue. Tubal ligation also appears to be more strongly inversely related to endometrioid than to some of the other ovarian subtypes (127). There has also been some consistency regarding mucinous tumors being distinctive, showing increased risks related to cigarette smoking (173) and decreased risks with use of menopausal hormones (171,221,222). Obesity also is beginning to emerge as an especially strong predictor for endometrioid cancers (100,223).

It is clear that further leads regarding etiologic heterogeneity will depend on either large studies or more likely on consortial efforts that bring together data from multiple epidemiologic studies. Such efforts are currently underway by several groups and should provide further insights as to possibly distinct origins of some of these tumor subtypes.

Conclusions

Much of the clinical and epidemiologic evidence concerning risk factors for ovarian cancer implicates ovulatory activity (Table 1.2). Conditions associated with reduced ovulation, for example, pregnancy and oral contraceptives, consistently reduce risk. Combining these and other menstrual factors into single “ovulatory age” or “lifetime ovulatory cycles” indexes has generally produced the expected associations with ovarian cancer risk; that is, older ovulatory ages (224) or higher cycle counts (225) increase risk. However, the misclassification inherent in these indexes is sufficient to generate different risk estimates (226), and the magnitude of risk reduction for short-term oral contraceptive use or a single pregnancy exceeds the proportional decrease in ovulatory cycles that would be expected to be associated with these exposures.

Table 1.2 Risk Factors for Ovarian Cancer

Factors Influencing Risk	Estimated Relative Risk ^a
Demographic factors	
Older age	3.0
Residency in North America, Northern Europe	2.0–5.0
Higher levels of education or income	1.5–2.0
White ethnicity	1.5
Exposures that increase risk	
Nulligravida	2.0–3.0
History of infertility	2.0–5.0
Early age at menarche	1.5
Late age at natural menopause	1.5–2.0
Long-term use of menopausal estrogens	3.0–5.0
Perineal talc exposure	1.5–2.0
Female relative with ovarian cancer	3.0–4.0
Endometriosis	1.5–2.0
Pelvic Inflammatory Disease	1.5–2.0
Exposures that decrease risk	
History of hysterectomy or tubal ligation	0.5–0.7
Use of oral contraceptives	0.3–0.5

^aRelative risks depend on the study and referent group employed.

The putative mechanisms behind ovulatory inhibition and the risk associated with “increased ovulation” (227) raise additional questions. An early report suggested, based on the associations with parity and infertility, that an unidentified endocrine abnormality predisposed women to relative or absolute infertility and ovarian cancer. The protection associated with oral contraceptives seems unlikely to fit this hypothesis unless, in some improbable manner, their use induces an endocrine milieu similar to that underlying fertility.

A second popular unifying hypothesis is that ovarian cancer is the result of accumulated exposure to circulating pituitary gonadotropins (228). Although this is consistent with the parity, menopause, and oral contraceptive associations, a study that directly measured gonadotropin levels failed to find a relationship with subsequent development of ovarian cancer (141). This theory also fails to account for the risks associated with clinical infertility, and it predicts that menopausal hormone therapy would decrease risk, because both exposures are associated with reduced gonadotropin levels.

A third explanation points to a biologic effect of ovulation on ovarian surface epithelium. Ovulation prompts a cascade of epithelial events, including minor trauma, increased local concentrations of estrogen-rich follicular fluid, and increased epithelial proliferation. Such proliferation, particularly near the point of ovulation, can recruit inclusions into the ovarian parenchyma. Some or all of these “incessant ovulation” events may lie on the causal path to ovarian cancer (229,230). This is consistent with most of the endocrine-related risk factors except for the risks associated with clinical infertility.

Although it has been hypothesized that epithelial inclusion cysts give rise to ovarian tumors, cancer precursors of ovarian surface epithelium remain unclear and progress in understanding ovarian carcinogenesis, as previously mentioned, is partly limited by this lack of clarity on the tissue of origin of ovarian epithelial carcinomas. Nearly all other epithelial gynecologic cancers arise via a sequence of events whereby the normal epithelium undergoes conversion to a precursor lesion that can then become an invasive neoplasia. Cervical intraepithelial neoplasia, the precursor of cervical cancer, is probably the most well-known example. More recently, increasing evidence indicates that at least a subset of high-grade serous ovarian cancers arise from high-grade intraepithelial serous carcinomas in the fallopian tube fimbria and spread to the ovary (220). This could help explain the inconsistent reduced risks associated with tubal ligation and hysterectomy, given that the fallopian tubes would be removed only in a subset of these procedures.

No single theory adequately incorporates the available data. A unifying hypothesis may lie in a combination of ovulation, hormones, and local effects. Additional factors, such as genetic alterations; androgens, progestagens, and other hormones (227); inflammation (128); and endometriosis (152), also appear to be important.

Each hypothesis identifies testable possibilities. Discriminating between the roles of voluntary versus involuntary infertility could identify the mechanisms underlying the role of parity. Characterizing the specific reproductive abnormalities associated with clinical infertility could reveal new biologic mechanisms involved in ovarian carcinogenesis. Exploring the interactive contributions of the hormones along the hypothalamic–pituitary–gonadal axis could explain how specific hormones seem to influence risk at different time periods. In addition, verifying that inflammation or related conditions and pathways play an etiologic role in ovarian carcinogenesis could open new lines of inquiry.

Ovarian cancer epidemiology presents both simple and complex patterns. Rates have slowly declined over the last 40 years, and virtually all studies show consistent associations with some exposures, such as oral contraceptives, parity, and family history. But where some uncertainty exists, it is substantial. For example,

reproductive or lifestyle factors that are consistently associated with other reproductive cancers—smoking, obesity, menopausal hormone therapy—have been published with such diversity that traditional attempts to summarize quantitatively the divergent data likely will not prove to be useful. Although it is tempting to attribute the differences to histology-specific associations, such hypotheses will require substantially more epidemiologic, clinical, genetic, and transitional data before their acceptance is certain.

The highly penetrant genes account for only a small proportion (10%) of women who develop ovarian cancer, but a better understanding of the mechanisms behind those risks could introduce immediate benefits for high-risk women. A clear picture has emerged for some protective factors, such as oral contraceptives and parity, but risk associated with other important public health issues, such as smoking, obesity, and physical activity, remains uncertain. Continued attempts to account for the differences between studies should help delineate the spurious associations from the etiologically relevant risk factors. Doing so should help identify targets for improving detection, treatment, and prevention of this deadly tumor.

CERVICAL CANCER

Chronic persistent infection with carcinogenic genotypes of sexually transmitted human papillomavirus (HPV) is the causative agent of virtually all cases of cervical cancer (231). Of the more than 150 genotypes of HPV, several dozen can infect the anogenital epithelium and more than 15 (including HPV 16, 18, 26, 31, 33, 35, 39, 45, 51, 52, 56, 58, 59, 66, 68, 73, 82) can cause anogenital cancer. Individual genotypes differ greatly in carcinogenic risk, and HPV16 is by far the most carcinogenic type, accounting for half of cervical cancer cases globally (231,232). Reflective of the “necessary, but not sufficient” role of HPV in the causation of cervical cancer, several other etiologic cofactors are involved. The remarkable body of evidence developed over the past three decades in the understanding of HPV epidemiology has provided transformative clinical applications aimed at cervical cancer prevention and control. The pathogenesis, diagnosis, and prevention aspects of cervical cancer are detailed in Chapter 7. The current chapter will concentrate mainly on the descriptive epidemiology of invasive cervical cancer, the natural history of HPV infection, and the broad relationships with major etiologic risk factors.

Demographic Patterns: Global and United States

According to the latest global data compiled by the IARC, cervical cancer is the third most common cancer (after breast and colorectal cancers) among women worldwide (233,234). It is the first or the second most common (after breast cancer) in less-developed countries. There were more than 529,000 incident cases estimated in 2008 and a 5-year prevalence of more than 1.5 million cases (233). Cervical cancer accounted for approximately 275,000 deaths worldwide in 2008, or just under one tenth of the total number of female cancer deaths (233). The cancer burden (incidence and mortality) is disproportionately high (greater than 85%) in the developing world.

The incidence rate per 100,000 women-years for invasive cervical cancer in various geographic areas is highly variable, reflective of differences in HPV infection and access to screening services (234) (Figs. 1.7 and 1.8). The highest age-standardized rates were reported from sub-Saharan Africa (31.7 per 100,000), with some countries (Guinea, Zambia, Comoros, Tanzania, Malawi, Mozambique, and Swaziland) having rates

FIGURE 1.7. Global incidence of cervical cancer: Geographic distribution of the world age-standardized incidence rate of cervical cancer, by country, estimated for 2008 (per 100,000 women/year). The counts in parentheses in the legend correspond to the number of countries in each ASIR range.

higher than 50 per 100,000. Other regions of the developing world, including South Central Asia (24.6), Latin America and the Caribbean (23.5), and the Pacific Islands (23.7), also have high burdens. The case burden of disease as reflected by annual new incident cases and deaths due to cervical cancer is highest in India (>134,000 cases and >72,000 deaths), followed by China, Brazil, Bangladesh, and Nigeria (233). An analysis of population-based surveys from 57 representative countries has indicated that the coverage of cervical cancer screening in developing countries is on average 19%, compared to 63% in developed countries, and there is a wide variation in coverage levels within developing countries (235) (Fig 1.8).

An examination of age-specific cervical cancer incidence, in countries prior to introduction of screening has demonstrated that the median age of cervical cancer diagnosis worldwide is between 40 and 60 years (mean ~50 years). Rates begin to increase around age 25, with an unusually early plateau or peak starting at age 40 to 50 (236). Incidence rates increase with age, and the age structure reflects that cervical cancers originate from HPV infections transmitted mainly in late adolescence and early adulthood.

It is reported that 12,710 women were diagnosed with and 4,290 died from cervical cancer during 2011 in the U.S. (237). The overall age-adjusted incidence rates for invasive cervical cancer based on SEER data suggest an incidence rate of 8.1 per 100,000 women for the period 2004 to 2008 (238). Regional differences in incidence, with excesses particularly in underserved regions in the Southeastern and Southwestern U.S. are apparent (239). Substantial racial/ethnic differences in incidence rates persist. Compared with Whites and Asian and Pacific Islanders, incidence rates were higher among Black, American Indian and Alaska Native, and Hispanic women (239) (Fig 1.9).

Cervical cancer rates began to fall during the early twentieth century, even before the advent of cytologic screening. Reduced parity may have contributed to this pattern, given that

multiparity appears to be a cofactor for progression of HPV infection to cervical neoplasia. In the latter half of the last century, effective screening contributed to a further reduction in cancer incidence and mortality, particularly among women aged between 30 and 74 years, because of targeting of this age group in many countries (Fig. 1.10).

In the U.S. and many other developed nations, rates of squamous cell carcinomas, accounting for approximately 80% of invasive cervical cancers, have declined steadily since the introduction of Pap smear screening, while adenocarcinomas (accounting for approximately 15%) have not (240,241). In fact, rates of cervical adenocarcinomas have risen in the past two to three decades in various countries, including the U.S., relative to both rates and absolute numbers of squamous cell carcinomas.

The 5-year survival rate for cervical cancer is 67.9% (238), with survival being highly dependent on stage at diagnosis. Younger women and White women are more likely than older women and Black and Hispanic women, respectively, to be diagnosed with localized cancer, which carries a good prognosis.

Human Papillomavirus

For more than a century, epidemiologic studies have suggested an association between sexual activity and cervical cancer, but proof that HPV is the sexually transmitted agent responsible for this association was not achieved until sensitive methods for detecting HPV DNA were developed. The recognition of the key etiologic role of HPV infection has profoundly altered the epidemiologic study of cervical cancer. The epidemiologic association between HPV infection and cervical cancer fulfills all of the established epidemiologic criteria for causality. As a result, HPV is now accepted to be the central, necessary causal factor for virtually all cases of cervical cancer in the world (231,242). It is increasingly clear which previously “established” epidemiologic

risk factors for cervical cancer are correlates of HPV infection, which lead to infection, and which are cofactors operating only in the presence of HPV infection. An indirect proof for this is since HPV is transmitted by direct physical sexual contact, virgins (women without any sexual contact at all) almost invariably test negative for HPV, which explains their virtually negligible risk of cervical cancer regardless of other behaviors (243).

Cervical HPV transmission, which is primarily sexual, is studied best at the molecular level, primarily because genotypic heterogeneity informs risk stratification. Moreover, before development of precancerous stages, most infections are not microscopically or macroscopically evident. Each HPV type is a separate genetic species, and should be considered a separate sexually transmitted infection. Because all carcinogenic types are transmitted by the same sexual route, concurrent multiple-type infections are common. The available data, which are limited, seem to indicate that prevalent HPV types influence each other minimally (244).

The epidemiology of cervical cancer is most coherently understood in terms of the natural history of cervical carcinogenic HPV infection, which can be broadly categorized in the following stages: (a) exposure/acquisition of new HPV infection with clearance of a majority of the infection, (b) persistence of HPV infection and progression to precancerous lesions (cervical intraepithelial neoplasia 3 [CIN3]), and (c) development of invasion (Fig. 1.11) (236).

As the most common sexually transmitted infection, HPV infection is similar to other sexually transmitted infections, with a large peak following sexual initiation. Cervical HPV infections

tend to clear after 6 to 24 months, as do warts anywhere on the body (244). Acquisition and clearance dynamically oppose each other in each cohort of women to produce the characteristic age distributions as infections are transmitted sexually when women have new partners and are then cleared (245). Transient HPV infections are ubiquitous among sexually active young women, but progression to a cervical cancer precursor requires persistence of carcinogenic types. It is the *overt persistence* of one of the carcinogenic types that is strongly linked to precancer, which histologically corresponds to CIN3, including carcinoma *in situ* (246). Persistence of carcinogenic types of HPV and development of precancer are not identical but, thus far, they are so closely linked that epidemiologists are only beginning to disentangle them. Part of the problem is that precancers begin as extremely small clonal lesions that may be below the limits of detection of microscopy (247).

The distribution of HPV types in cervical cancer has been extensively studied in the U.S. and international collaborative studies (248–251). The most common HPV types in descending order of frequency are HPV types 16, 18, 45, 31, 33, 52, 58 and 35, together responsible for approximately 90% of all cervical cancers worldwide. Persistent HPV16 infection is an extremely strong risk factor for subsequent diagnosis of CIN3 and invasive cancer and has been classified as a Class 1 human carcinogen by the IARC (231). HPV types are more predictive of risk than subtleties of minor and equivocal cytopathic effects, colposcopic findings, or behavioral cofactors like smoking. Furthermore, intratypic sequence variants of HPV 16 and possibly other types have been associated with altered risk, although these risk modifications are weaker than the intertypic variation (252). The role of elevated viral load (i.e., HPV content

FIGURE 1.11. An epidemiologic model of the natural history of cervical carcinogenesis. The major steps in cervical carcinogenesis can be broadly categorized in the following stages: (I) exposure/acquisition of new human papillomavirus (HPV) infection that may cause transient cytological changes, a majority of which clear spontaneously; (II) persistence of few carcinogenic HPV infections and progression to precancerous lesions (cervical intraepithelial neoplasia 3 [CIN3]); and (III) development of invasion. The pictures in the top row show cytological changes and those in the bottom row show corresponding colposcopic impressions of the various stages of the natural history of cervical carcinogenesis.

in samples obtained from infected women) in predicting persistence and progression of infection is complicated and varies by HPV type (253). A clear trend of increasing prospective risk with increasing viral load has been demonstrated only for HPV16. Viral load assessment is not useful clinically (254). Although studies suggest that women with prevalent infections may be more likely to acquire additional infections, infection with one HPV type does not seem to influence the risk of persistence and development of precancer from another concurrent infection (244).

HPV type greatly affects both the absolute risk of viral persistence and of progression to precancer associated with viral persistence (255,256). The most common carcinogenic type, HPV16, is also the most common type in the general population, linked to its greater propensity to persist (247,256). Although certain noncarcinogenic types (e.g., HPV61) can also be persistent and common, they do not cause malignant transformation (256,257). The average time of viral persistence that leads to diagnosable precancer is not clear. The average age at microscopic diagnosis of precancer is approximately 25 to 30 years (258), approximately 5 to 10 years after the average peak ages of carcinogenic HPV prevalence and associated minor cytologic abnormalities in screening populations. Biomarkers that predict persistence of cervical precancer and offer better discrimination of transforming versus transient HPV infections are increasingly available (259). Because the presence of HPV DNA is not specific enough to predict persistent HPV infection, other newer biomarkers such as the use of cellular correlates (e.g., p16^{INK4a} and ki-67) of increased expression of viral oncoproteins or increased expression of HPV viral oncogenic transcripts (e.g., E6/E7 mRNA) can allow triage for colposcopy after a mildly abnormal or borderline cytology or a positive HPV DNA test (259). The advances in cancer epigenetics have led to a strong focus on methylation-based biomarkers for many cancer sites, including the cervix. In addition, several recurring chromosomal imbalances have been observed for cervical precancer and are currently being explored as biomarkers along with other newer approaches such as micro-RNAs (miRNA) and proteomics (259).

Noncarcinogenic HPV infections are capable of producing lesions falsely diagnosed as precancer, especially CIN2, showing that this level of abnormality is not a perfect surrogate for cancer risk (260). Still, because of the U.S. emphasis on safety and concern over loss to follow-up, treating precancer (except as appropriate in very young women, etc.) is a valid clinical strategy to provide a margin of safety, given that it is not yet possible to know which lesions pose a threat. Eventually, better accuracy based on molecular profiling is the goal.

The immune response to HPV is an important determinant of viral clearance versus persistence and, by extension, a major determinant of cervical cancer risk (261). However, despite our growing understanding, many aspects of the interactions between HPV and the host immune system remain unknown (262). The key immune responses involved in the clearance of HPV infections are known to be cell-mediated, although neutralizing antibodies are highly protective after immunization with HPV virus-like-particle (VLP)-based vaccines (263). The immune response to naturally acquired HPV infection has not been quantified adequately and is difficult to study given the lack of site-specificity, challenges in serological assay development and validation, and the fact that seronegativity might not always reflect susceptibility. Responses to measure HPV vaccine responses, on the other hand, have been extensively developed and are currently being standardized for facilitating international epidemiology studies and future vaccine development and evaluation (264).

A major unresolved question of HPV natural history relates to the lack of understanding of viral latency (265). In long-term studies, virtually all HPV infections become undetectable by sensitive HPV DNA tests, usually within 2 years, except for those that lead to precancer. However, it is unknown if this lack of detection reflects true virological clearance or a latent stage due to immunologic control that permits long-term presence (latency) below levels of detection. Indeed, neither the cause of reemergence (reactivation) of viral types seen in immunocompromised individuals (e.g., transplant patients and HIV-immunosuppressed women) is known, nor is the clinical significance of latency in terms of the fraction that can progress to precancers and cancers clear (265). In the era of HPV vaccination, many of these issues will acquire increased significance, especially with the emergence of HPV genotyping assays in clinical practice.

Precancerous lesions (CIN3, in particular) tend not to regress over short-term follow-up; however, even among precancerous lesions, risk and timing of invasion versus eventual regression are matters of probability. The absolute risk of untreated precancer developing into invasive disease is argued, with estimates averaging 30% but ranging from 10% to 90% (266). The high ratio of precancerous lesions to cancers supports the belief that many cases of precancer, particularly CIN2, would not invade but rather would regress if followed for many years. Screened detected cases of invasive cancer, on average, occur approximately 15 to 20 years or later than precancer, suggesting a long sojourn time in the precancerous state (236). The median age moves toward even older ages as the quality of screening decreases, and

the average stage of cancer at diagnosis also worsens due to this diagnostic delay.

Cofactors Influencing Risk of Persistence of Carcinogenic HPV Infection and Progression of Cervical Precancer to Cancer

Given that carcinogenic HPV infection is a necessary and critical, although not sufficient, factor in the cervical carcinogenic processes, there has been substantial exploration of cofactors that influence the individual woman's risk for viral persistence, development of precancerous lesions, and finally invasion. Indeed, extensive epidemiologic investigations of a number of these risk factors (especially sexual behavior, parity, and smoking) were conducted even in the pre-HPV era. Some of these factors and the evidence supporting them are discussed in this section.

Sexual Behavior

HPV is highly transmissible via sexual contact in both genders. Numerous epidemiologic studies have shown that markers of sexual activity, such as number of sexual partners (recent or lifetime), are among the most important cofactors for HPV detection and subsequent risk of cervical precancer and cancer (267). HPV infections are easily transmitted with few acts of sexual intercourse and, therefore, sexual frequency is not a major risk factor for cervical neoplasia. The age at sexual debut serves as an apparent proxy for the time of HPV infection (268), and an early age of debut reflects higher risk, also accentuated by greater cervical ectopy during adolescence (269).

A protective effect against cervical cancer risk has been noted for careful, consistent condom use. Condom use affords modest protection against HPV infection and resultant external warts (HPV6 and HPV11) and cervical lesions caused by carcinogenic HPV types (270). Given that users of condoms may not report sporadic unprotected contacts, and that the entire skin and mucosal genital area at risk for infection is not protected with this contraceptive method, only modest protection against transmission would be expected (271).

HPV infection transmitted from a male partner to his female partner can be seen as "the male factor" for cervical cancer (272). Confirmed associations supporting this view include the geographic clustering of cervical and penile cancer, the increased risk of cervical cancer among wives of men who have penile cancer, the increased risk among partners of men who have had a previous partner who died of cervical cancer, and the increased risk among women whose partners travel (273). Circumcision is associated with a reduced risk of HPV detection in penile samples, and the wives of men with a history of multiple partners were at lower risk of cervical cancer if the men had been circumcised (273,274). Circumcision is associated with reduced prevalent male HPV infection, and randomized clinical trial evidence from Africa has now shown that voluntary adult male circumcision reduces transmission between sexual partners (274,275).

Parity and Other Obstetrical and Gynecologic Events

HPV-infected women who have many live births are at increased risk of cervical cancer and precancer. There is a dose-dependent increase in risk with numbers of live births, most evident among women with many live births. Although this epidemiologic association is firmly established, the explanatory mechanism is

not clear. Mechanisms underlying the association between parity and cervical neoplasia include trauma during parturition, hormonal changes associated with pregnancy, immunosuppression, and possibly altered anatomy of the transformation zone, specifically eversion. Other menstrual and reproductive factors, including miscarriages, abortions, stillbirths, ectopic pregnancies, cesarean sections, age at first pregnancy, age at menarche, and age at menopause, are not independently associated with risk (276,277).

Contraceptives

Studies examining the relationship of oral contraceptive use to cervical cancer risk among HPV-infected women are especially complex, with questions arising about the potential for confounding, particularly by the duration of HPV infection and screening behavior (278). Use of oral contraceptives could plausibly potentiate the carcinogenicity of HPV infection, because transcriptional regulatory regions of HPV DNA contain hormone-recognition elements and transformation of cells *in vitro* with viral DNA enhanced by hormones (279). Pooled analyses from multicenter case-control studies found an elevated risk of invasive cervical cancer among HPV-positive women who used oral contraceptives for more than 10 years (278). Shorter durations of use were not associated with elevated risk. Evidence linking oral contraceptives to cervical abnormalities has raised concern about long-acting steroid preparations, notably depot-medroxyprogesterone acetate (DMPA). Although these agents are widely used in many countries, studies evaluating their effects, particularly among HPV infected women, are limited (280).

A recent pooled analysis of ten case-control studies of cervical cancer and 16 HPV prevalence surveys from four continents has shown that intrauterine device (IUD) use, a common contraception option in developing countries, was associated with a lower risk of cervical cancer, regardless of duration of use (few months to 9 years) and after adjustment for screening status (281). This evidence contradicts a widely held assumption that IUDs may increase the risk of cervical cancer, and might suggest their role as protective cofactors in cervical carcinogenesis, much like a similar role they play in protecting against endometrial cancer. While the precise mechanisms are subject to future investigations, it has been suggested that local cellular immunity is triggered during the process of IUD insertion or by the device itself. That said, evidence from a recent study in female rhesus macaques has suggested that cervical microtrauma during collection of cytological smears actually increases the number of HPV infectious events (282).

Socioeconomic Status

Internationally, women defined as belonging to low social class were found in a meta-analysis to have twice the risk of cervical cancer compared to women defined as belonging to a high social class (283). In the U.S., a recent analysis of county-level incidence data noted that poverty-associated, infrequent screening leads to suboptimal stage at diagnosis profiles, resulting in elevated incidence and mortality rates. Some of these affected areas included Appalachia, the southeastern Atlantic states, and the lower Mississippi Valley, as well as central counties of large metropolitan areas (239).

Cigarette Smoking

Several case-control and cohort studies, as well as collaborative pooled analyses and registry linkage studies, among groups of women infected with carcinogenic HPV have shown that smokers are at increased risk compared with infected women who do not smoke (284,285). Current smoking is the main risk factor,

not past smoking, with no clear trend with time since stopping smoking. Among current smokers, evidence of increasing risk has been found with increasing intensity and duration (or early start) of smoking. Several investigations have attempted to define possible mechanisms by which smoking might alter cervical epithelium (286). Some investigations have looked into measurement of tobacco-driven carcinogens such as polycyclic aromatic hydrocarbon-DNA adducts in cervical tissue of HPV-infected women (287). The immunosuppressive effects of smoking may cause disturbance in the early immune responses or increase persistence through increased production of reactive oxygen species (288).

Host Factors

Whereas humoral (antibody-mediated) immunity appears to play a central role in preventing HPV infection (as in prophylactic vaccines), elimination of HPV seems more closely related to mounting an effective cellular immune response (262). Impaired cellular immunity, attributable to human immunodeficiency virus (HIV) infection, transplantation, or immunosuppressive drugs, has been shown to increase HPV prevalence, persistence, warts, CIN, and cancer (289,290). In contrast, deficiencies in humoral immunity appear unrelated to these conditions.

Polymorphisms in the human leukocyte antigen (HLA) genes have been implicated in the risk of HPV-associated diseases. HLAs are important determinants of the efficiency of antigen presentation to immune effector cells and, therefore, may influence the outcome of HPV infections (291). Both Class I HLA genes (those that encode HLA molecules that are present in all nucleated cells) and Class II HLA genes (those that encode HLA molecules that are present in lymphocytes and other immune-related cells) are involved in immune presentation (277). To date, HLA Class II genes have been more extensively studied than HLA Class I genes for their association with cervical cancer. A protective role for HLA DRB1*13 in cervical cancer has been consistently described in several populations. Activating combinations of HLA Class I alleles and the killer immunoglobulin-like receptor confers susceptibility to cervical cancer, whereas inhibitory combinations are associated with protection against the disease (291).

Although the biological basis is unknown, studies from nationwide tumor, twin, and other family registries in Scandinavian countries indicate that cervical cancer aggregates in families (292). In general, an approximate twofold increase in risk of precancer or invasive cervical cancer relative to general population risk is observed in family members of cervical cancer patients. It is not settled how much of this elevation in risk among relatives of individuals affected with cervical cancer can be attributed to shared environment versus genetic effects (292,293).

Nutrients

The influence of nutrient status on risk of cervical neoplasia has received substantial research attention. While dietary factors such as antioxidant micronutrient intake are likely important in cervical carcinogenesis, methodological difficulties prevent establishment of firm associations between a specific aspect of nutritional status and HPV infection or cervical cancer risk. A recent meta-analysis of case-control studies have suggested preventive effects of micronutrients such as folic acid, vitamins B, C, and E, and beta-carotene (294). However, lack of prospective studies and randomized trials preclude definitive evidence regarding role of supplementation. The association of low folate levels and high homocysteine levels with risk of cervical cancer has led to interest in markers of one-carbon metabolism and DNA repair (259).

Infectious Agents Other than HPV

HPV infection is known to be the central, necessary cause of cervical cancer, but other sexually transmitted agents could increase the risk of cervical cancer among HPV-infected women. Of the other agents examined, herpes simplex virus (HSV-2) was originally hypothesized to play a central role, but most attention now is focused on *Chlamydia trachomatis*. Although residual confounding by some aspect of HPV infection has not been completely ruled out, despite adjusting for HPV exposure using DNA tests and/or serology, *Chlamydia trachomatis* seropositive women are at increased risk compared to seronegative women (295).

Women with HIV and acquired immunodeficiency syndrome (AIDS) have higher prevalence, incidence, and persistence of HPV infection and precancerous lesions, strongly associated with immunosuppression (296). It is also well established that the incidence of cervical cancer is increased several fold in both women with HIV/AIDS as well as those who are iatrogenically immunosuppressed (e.g., organ transplant recipients), thus reinforcing the primary mediating role of immunosuppression in increasing this risk (297). However, it is also hypothesized that interaction between HPV and HIV in the affected cervical tissue leads to the persistence of HPV infection and cervical neoplasia by various mechanisms including depletion of Langerhans cells (298), host immune response (299), or via proinflammatory cytokine expression (300). An alternative explanation is at the cellular level; HIV-specific Tat protein upregulates expression of HPV E6 and E7 oncogenes and enhances their oncogenic transformation efficacy (301). These two mechanisms are, however, not exclusive, and a joint effect(s) most likely takes place at early precancerous stages.

Risk Factors for Cervical Adenocarcinoma

While infection with a carcinogenic HPV is a necessary cause of both squamous cell carcinomas and adenocarcinomas, the distribution of carcinogenic HPV types and variants detected in these two tumor types vary (302). Multiple studies suggest that HPV18 accounts for a relatively higher percentage of adenocarcinomas as compared to squamous cell carcinomas (249), although more recent evidence is pointing to an increasingly equitable role of HPV18 as well as HPV16 (248,303).

Interpreting increasing rates of cervical adenocarcinomas over time poses challenges because of gradual improvements in clinical practices (including the use of devices to obtain better endocervical sampling), stricter criteria for adequate Pap tests, development of cytologic criteria for recognizing adenocarcinoma *in situ* (AIS) and, recently, formal inclusion of the AIS category in the new Bethesda System (304). In addition, proposed but unsubstantiated explanations for these upward trends include increased rates of HPV infection without improved cytologic detection of AIS, a specific increase in rates of HPV 18 infection, and increased exposure to HPV cofactors specific to adenocarcinoma (236).

Although our understanding of the etiology of cervical adenocarcinoma is incomplete, a picture is emerging in which adenocarcinoma seems to share some risk factors with cervical squamous carcinomas (acquisition of HPV through sexual contact) and others with uterine carcinoma (a tumor etiologically related to hormones). While adenocarcinoma has most risk factors in common with squamous cell carcinoma, an important exception is smoking, which does not seem to increase the risk for adenocarcinoma (305). In contrast, increased weight (or related measures) appears to be related to increases in the risk of cervical adenocarcinomas (306). Oral contraceptives and menopausal hormone therapy have been linked to an increased risk

for AIS or adenocarcinoma (307). The increased risk of cervical adenocarcinoma associated with obesity and reduced risk with smoking resemble the epidemiology of endometrial adenocarcinoma. However, the relationship between cervical adenocarcinoma and oral contraceptives is more similar to reported results for squamous carcinomas of the cervix.

Conclusions

Knowledge of the epidemiology of HPV and its causal role in cervical carcinogenesis has been successfully translated into clinical practice (232,308), particularly to reduce rates of squamous lesions. In many developed countries, newer consensus guidelines now encourage cotesting with HPV DNA testing and cytology to improve screening performance and reduce screening intervals, since a negative result provides strong reassurance that immediate follow up is not required and can reduce patient anxiety and health costs (308). Repeated HPV testing is also finding application in following women without intervention and in determining the risk of recurrence among those treated for CIN. Screening studies are underway to develop new approaches that optimize resource utilization. Finally, the increasing use of prophylactic HPV vaccines is expected to impact rates of cervical precancer in the coming years, although reduction in cancer incidence will take longer. Epidemiologic research on HPV and cervical cancer will remain integral to clinical practice recommendations and public health strategies, with a goal to improve patient management and guide and monitor successes in cervical cancer prevention and control.

VULVAR CANCER

Demographic Patterns and the Importance of Pathologic Classifications

Carcinoma of the vulva is a rare genital neoplasm with an average annual age-adjusted incidence in all SEER areas during 2004 to 2008 of 2.3 per 100,000 women (238,309). During 2012, an estimated 4,490 women developed the disease and 950 died as a consequence (1).

Vulvar cancer is etiologically heterogeneous, and pathologic subtypes have distinct epidemiologic features (310,311). The great majority of cases are squamous, but two subclassifications of squamous cancers, basaloid and warty, are more linked to HPV than keratinizing squamous tumors (312). Most vulvar intraepithelial neoplasias (VIN), similar to CIN, show risk factors that resemble basaloid and warty carcinomas. The HPV-associated subtypes are associated with younger age and Black ethnic group. The non-HPV-associated types are associated with chronic inflammatory states such as lichen sclerosus.

Because vulvar cancer is heterogeneous, and because epidemiologic data do not separate the subtypes, compiled data must be interpreted very cautiously, with the recognition that summaries can obscure subgroup differences. Although vulvar cancer has been noted in clinical series to occur frequently among Blacks, recent incidence data do not support any substantial differences in *overall* incidence by race (2.4 per 100,000 for White women and 1.8 per 100,000 for Black women) (238,309). Although the disease occurs primarily among older women (median age at diagnosis being 68 years), recent analyses of SEER data indicate substantial increases in the incidence of *in situ* vulvar carcinomas (mainly HPV-related), which generally occur at much younger ages than invasive diseases (313).

Cancer of the vulva occurs significantly more frequently among women with primary cancers of the cervix, and the two diseases often occur simultaneously. Approximately 15% to 20% of women with vulvar cancer have a second primary cancer occurring simultaneously or nonsimultaneously in the cervix, vagina, or anogenital area. As many as 10% to 15% of women with cancer of the vulva have a second primary lesion of the cervix (314). This association probably reflects multifocal HPV infection. When multiple primaries are not diagnosed simultaneously, cancer of the cervix usually precedes cancer of the vulva. Many patients with vulvar cancer have multifocal genital lesions, commonly including a mixture of condyloma acuminatum planum and intraepithelial neoplasia. They may also have similar changes at other anogenital sites, including the vagina, cervix, and perianal region (314).

Rates of vulvar cancer overall have remained relatively stable over the past 3 decades per SEER data (238,309). Given that *in situ* cancers develop on average significantly earlier than invasive vulvar cancers, it may be that changes in certain risk factors (e.g., increased sexual activity and HPV infection) may have been too recent in order for effects to be seen for invasive cancers. Alternatively, successful treatment of *in situ* tumors may have prevented the occurrence of invasive disease. Again, the most likely explanation for the patterns observed is etiologic differences, with HPV being more important for *in situ* cancers.

Risk Factors

While early case-control studies reported higher risks among women reporting multiple sexual partners, subsequent studies postulated a role for HPV in the etiology of the tumors, finding high rates of detection of the virus in vulvar tumor tissue and high subsequent disease risks among patients with seropositive tests to HPV16 (315). HPV16 appears to be the predominant type detected among vulvar cancer patients (316). Studies have found particularly high risks associated with HPV seropositivity among cigarette smokers, suggesting that the effect of HPV may depend on smoking as a cofactor (317,318).

Although the incidence of vulvar cancer has been previously thought to be related to social class, results from one case-control study indicated that control for sexual factors eliminated this effect (319). Suggestions that the risk of vulvar cancer is elevated among nulliparous women and those with late ages at first birth were not confirmed in this study.

Vulvar carcinomas often arise within genital warts, but more specific temporal associations between the two remain unclear. Several studies have suggested that a history of vulvar and anogenital warts is associated with an elevated risk of vulvar cancer (320). However, the HPV types that cause vulvar warts, HPV6 and HPV11, are not genetically close to the major types in vulvar cancers (predominantly HPV16), so the exact relationship between warts and cancer is somewhat obscure.

Several clinical studies have suggested that vulvar cancer may be elevated among women with diabetes, obesity, or hypertension, and among users of oral contraceptives. However, these findings have not been definitively confirmed in epidemiologic studies. While certain immunosuppressed populations, such as HIV-infected women, also have high prevalence of anogenital warts and VIN, regression is still common and vulvar cancers are infrequent (297,321). Recent attention has also focused on the possible etiologic role of genetic and local inflammatory factors in pathogenesis of VIN and invasive vulvar carcinoma (322,323).

Conclusions

The cervix and vulva are covered by squamous-cell epithelium with a common embryologic origin from the cloacogenic

membrane. These similarities have led to the theory that the entire lower genital tract responds to various carcinogens as a single tissue field, resulting in a relatively high proportion of multicentric squamous carcinomas. The multicentric nature of the disease; its association with cervical, vaginal, and perianal malignancies; and several risk factors common to it and cervical cancer suggest that the etiologic mechanisms for a fraction of vulvar cancer and cervical cancer may be similar, linked to HPV infection.

VAGINAL CANCER

Demographic Patterns

Cancer of the vagina is also rare, with an average annual age-adjusted incidence of 0.7 per 100,000 women in the SEER areas for the period 2000 to 2004. In contrast to vulvar cancers, the incidence is higher for Blacks (1.0 per 100,000 for Blacks vs. 0.7 per 100,000 for Whites), but the reasons for the discrepancy are unknown. During 2012 it is estimated that 2,680 women developed the disease and 840 died from it (1). The average 5-year survival rate is 52% for Whites (50% for all races). The majority of vaginal cancers are squamous cell carcinomas and occur in the upper part of the vagina.

Vaginal cancer is primarily a disease of older women, with almost 60% occurring among women 60 years of age or older (324). In the past, carcinoma of the vagina was only rarely reported in infants and children but, beginning in the late 1960s, cases of clear cell adenocarcinoma of the vagina, an uncommon cancer in any age group, began to be observed with much greater frequency than expected among women between 15 and 22 years of age. Most of these cases have been linked to prenatal exposure to diethylstilbestrol (DES) (325).

Risk Factors

The rarity of vaginal cancer has limited the conduct of definitive epidemiologic investigations. A case-control study of vaginal cancer, based on relatively few cases, found associations of risk with low socioeconomic status, histories of genital warts or other genital irritations, and previous abnormal Pap smears (326). A more recent and larger study linked risk with histories of multiple sexual partners, early ages at first intercourse, and current cigarette smoking (327). Epidemiologic studies have also shown high risks associated with prior hysterectomies, although this apparently is due to the predisposition of women with anogenital cancers (particularly those with cervical cancer) to subsequently develop vaginal cancers (328).

HPV Infection

Findings that vaginal cancer is frequently found as a synchronous or a metachronous neoplasm with cervical cancer have led to the suggestion that there may be shared etiologic features between vaginal and cervical cancers (328). HPV has been related to disease risk through findings of HPV antigens or DNA in vaginal cancer tissue (329). HPV DNA has been reported in tumor blocks of greater than 80% of patients with *in situ* and greater than 60% of patients with invasive cancers (330). In addition, serologic antibodies to HPV have been linked to subsequent disease risk.

Diethylstilbestrol and Vaginal Clear-Cell Adenocarcinomas

In 1971, seven clear cell carcinomas of the vagina and one closely related endometrioid carcinoma were observed in young women (15 to 22 years of age) (331). An epidemiologic study found that the mothers of seven of the eight women had taken DES during the first trimester of pregnancy as opposed to none of the mothers of 32 matched controls. The relationship between DES exposure *in utero* and adenocarcinoma of the vagina was soon confirmed in New York State and at the Mayo Clinic. A registry of clear cell cancer of the vagina and cervix has been established, and many more cases have been reported (332). Among these patients, about twice as many have clear cell adenocarcinoma of the vagina as have clear cell adenocarcinoma of the cervix.

Recent data from an assembly of all established DES cohorts indicate that the majority of patients with vaginal or cervical adenocarcinomas are diagnosed prior to age 25, with the incidence after this age decreasing by 80% (333). The estimated rate for clear cell adenocarcinoma of the vagina and cervix through 39 years of age was estimated to be 1.6 per 1,000 DES-exposed daughters (325). Thus, DES exposure leads to a large relative increase in risk, but it affects only a small proportion of all exposed women. It remains to be seen what risk will be encountered by DES daughters when they reach their fifties and sixties, the peak ages of adenocarcinomas of the vagina in women unexposed to DES (325). When assessing a woman's cancer risk, whether her mother took DES in pregnancy might still be a relevant aspect of the medical history for women born during the period of DES use in pregnancy (331).

Conclusions

Less is known about risk factors for vaginal cancer than is known for vulvar cancer. It has recently been suggested that there may be two types of vaginal cancers with age-related etiology (333). In young patients, the etiology may be similar to cervical cancer and related to HPV, smoking, and low socioeconomic status, while the most common occurrences in older women may be due to hormonal factors or trauma to the vagina. Further attention should focus on the relative contributions of these factors.

The rare occurrence of vaginal adenocarcinoma in young women is distinctive in being essentially an iatrogenic disease related to *in utero* exposure to DES and other estrogens (325). A proposed mechanism involves nests of abnormal cells of müllerian duct origin, which are stimulated by endogenous hormones during puberty and promoted into adenocarcinomas.

GESTATIONAL TROPHOBLASTIC DISEASES

Gestational trophoblastic diseases (GTDs) (which include hydatidiform moles, invasive moles, and choriocarcinoma) encompass a range of interrelated conditions characterized by abnormal growth of chorionic tissues with various propensities for local invasion and metastasis (334,335). Hydatidiform moles can be either complete or partial and have distinctive pathologies and etiologies. Complete moles have paternally derived nuclear DNA but maternally derived cytoplasmic DNA. In contrast, partial moles generally have a triploid karyotype, with the extra haploid set of chromosomes being of paternal origin.

Demographic Patterns

Choriocarcinoma is a rare malignancy in the United States, with a reported incidence in all SEER areas of 0.1 per 100,000 women, or approximately 1 per 25,674 live births (336). Hydatidiform mole occurs about once in every 1,000 pregnancies, and approximately one of six occurrences results in invasive complications (either invasive mole or choriocarcinoma). Trophoblastic diseases have been reported to be more common in certain parts of the world, although some of the differences may be due to a variety of selection, detection, and reporting biases (337), including whether risk is expressed in relation to women at risk, conceptions, or live births. In the U.S., incidence rates have declined over time, and survival improved, but Blacks continue to have higher incidence and lower survival than women of other ethnicities.

The epidemiologic study of choriocarcinoma has been complicated by its relative infrequency. Most studies have, therefore, focused on defining risk factors for hydatidiform moles, but it is uncertain the extent to which these findings can be extrapolated to malignant trophoblastic disease.

Host Factors

Trophoblastic disease rates are considerably higher in Asian and African countries, but the true extent of difference from Western rates is difficult to decipher because of variations in reporting practices (338). In Europe and North America, the incidence of hydatidiform mole ranges from 0.57 to 1.1 per 1,000 pregnancies, while in Southeast Asia and Japan the incidence is closer to 2.0 (334). Corresponding incidence rates in the two parts of the world for choriocarcinoma are 1 versus 9.3 per 40,000 pregnancies. These differences persist in migrants, with one study showing that the incidence of GTDs in Asians was nearly twice as high as among non-Asians (339). One survey in the U.S. showed that even after adjustment for age and birth distribution effects, Blacks had a 2.1-fold greater risk and other non-White races had a 1.8-fold greater risk than Whites (340). American Indian and Alaskan native populations have also been shown to have high rates of GTDs (341).

One clearly established risk factor for choriocarcinoma and hydatidiform mole is maternal age. Women with extreme maternal ages (either very early or late) have nearly two-fold elevated rates, with even further age differences noted for the occurrence of complete moles (339). The recent increase in incidence of GTDs in certain European countries has been attributed in large part to increases in maternal ages (342,343).

A history of hydatidiform mole is also a strong risk factor. The risk of another molar pregnancy in a subsequent conception is approximately 1% (344), and the risk appears to increase to about 25% in women who have had more than one previous hydatidiform mole (345). One study suggested that some women might have multiple episodes of hydatidiform mole despite different male partners, suggesting either a role for oocyte defects or environmental factors (346). Familial clusters of biparental complete hydatidiform moles associated with novel missense NLRP7 gene mutations on chromosome 19q have recently been identified (347). Hydatidiform mole is associated with a 1,000 to 2,000 time increased risk for development of subsequent choriocarcinoma, with an even further enhancement after a complete molar pregnancy (2,500 times higher than after a live birth).

Two studies have found an association between blood group A and choriocarcinoma (348,349). The combination of mother's group A and father's group O generated over a 10-fold increased risk. Blood groups A and AB were associated with elevated risks of hydatidiform mole in one study but not in another (350,351). These findings may support a role for genetic

factors or immunologic factors related to the histocompatibility of maternal and trophoblastic tissues.

Menstrual, Reproductive, and Anthropometric Risk Factors

In several studies that have adjusted for the effects of late maternal age, parous women have remained at a substantially reduced risk of GTD compared with nulliparous women, with some evidence of further reductions in risk with multiple births (350,352,353). A number of studies have found an increased risk associated with a prior spontaneous abortion, although this has not been consistently observed (350,352–355). An increased risk of GTDs has been found in relation to a history of induced abortions in a number of studies, although information was not available on reasons for the terminations (352). A history of infertility has also been suggested as a risk factor for GTD, although not confirmed in all studies (350,352,355). In one study, Chinese patients reporting the use of herbal medicines during the first trimester of a previous pregnancy were at elevated risk (352).

Low body mass, unrelated to dieting or exercise, was reported as a risk factor for choriocarcinoma in one study (356). Patients also had late onset of menarche and lighter menstrual periods than controls, possibly reflecting lower estrogen levels.

Exogenous Hormones

Several studies have found an increased risk of trophoblastic diseases associated with long-term use of oral contraceptives (352,357,358). Two other case-control studies, however, found no influence of oral contraceptives on risk (350,355). In one study, the association was considerably stronger for partial than for complete moles (359). Others have suggested that oral contraceptives may increase the risk of malignant sequelae after mole evacuation through a tumor-stimulating effect (360,361). In one study, this effect was restricted to users of high-dose estrogens, although in others, there were no effects of the pill on postmolar complications (357,362,363).

Other Risk Factors

Late paternal age was suggested in one study to increase the risk of trophoblastic diseases, but other investigations failed to confirm this (350,352,364). Cigarette smoking has also been linked with the occurrence of trophoblastic disease (355). One study suggested that low carotene intake affected the risk of hydatidiform mole, but no specific dietary associations were observed in another study (352,357).

Conclusions

Although a genetic role in the development of hydatidiform mole is now certain, little is known about genotypes that predispose to hydatidiform mole or environmental factors that may increase the risk of defective ova. Except for the possible role of oral contraceptives, few potential environmental promoters have been identified.

The trophoblast plays an active role in pregnancy, including metabolizing and detoxifying xenobiotic substances, regulating nutrient and waste product transfer, synthesizing steroid and protein hormones, and controlling the immune response of the maternofetal unit. Injury to the trophoblast can occur in pregnancy as a result of environmental exposure (e.g., heavy metals and polycyclic hydrocarbons), resulting in the breakdown

of trophoblastic processes. When the trophoblast malfunctions, mutagenic, teratogenic, lethotoxic, and carcinogenic compounds gain access to the developing embryo, causing injury and death. The genotype of hydatidiform mole results in a trophoblast that malfunctions, and exposure to certain environmental agents during the molar pregnancy may promote choriocarcinoma. Before implantation, the trophoblast forms most of the embryonic tissue, which already metabolizes environmental agents. Even preimplanted moles, with their impaired metabolic capabilities, may increase the toxicity of environmental agents and promote carcinogenesis.

Recent advances in identifying genetic and molecular markers involved with partial versus complete moles (334,365) open a number of avenues for assessing the interaction of these markers with a variety of proposed environmental risk factors. This could include a focus on early stages in the disease process or on factors involved in the progression of molar pregnancies to more invasive complications.

SUMMARY

The goal of both medical practice and epidemiology is to reduce morbidity and mortality. For many diseases, the focus has turned to the ultimate aim of prevention. The link between identification of etiologic factors and possibilities for prevention is well illustrated for tobacco-and alcohol-related tumors and for those associated with specific pharmaceutical, radiogenic, and occupational exposures. Fortunately, for gynecologic cancers, there are a number of identified etiologic factors that are also amenable to preventive approaches.

Undoubtedly, the prospects for prevention are best for cervical cancer. For some time, secondary prevention in the form of screening for pathologic precursors of invasive disease has been the hallmark of the public health approach to this malignancy. The establishment of HPV as a central etiologic agent for the disease presents other avenues for prevention, including application of recently developed vaccines against the virus. Knowledge of when and how infection and other factors operate in the natural history of the disease has revolutionized screening strategies and shifted treatment from cell ablation to antiviral therapies. As always, combined laboratory, clinical, and epidemiologic research is needed to realize these propositions.

Many believe that more is known about the cause of uterine carcinoma than for almost any other tumor. A unified theory of how all risk factors may operate through a final common estrogenic pathway is popular and well supported. A woman's hormonal milieu may prove to be favorable to modification at a practical level. There is substantial evidence that elimination of obesity and a reduction in fat in the diet—two interventions actively promoted for other reasons—reduces endometrial cancer risk. After the epidemic of uterine cancer due to use of unopposed estrogen therapy, changes in the management of menopause occurred, resulting in a marked decline in the rates of uterine cancer. More care is devoted to identifying women who truly need estrogen therapy, treatment of menopausal

symptoms is for a much shorter period of time, the use of cyclic progestin in combination with estrogen is advised if indicated, and regular endometrial sampling is frequently practiced for long-term estrogen users.

Although past alterations in patient management led to a decline in uterine cancer, current events make future patterns less clear. Previous enthusiasm for long-term treatment of large segments of the population of menopausal women with hormones to control symptoms and prevent osteoporosis and heart disease may have implications for endometrial cancer in the future. On the other hand, current patterns of use of oral contraceptives could lead to reductions in endometrial cancer rates in the general population. The impact of widespread oral contraceptive use at young ages on endometrial cancer risk at older ages is not well studied. However, if it is anywhere near the reduced risk seen at young ages, the resulting reduction in uterine cancer overall could be substantial.

With further research, it is also possible that pharmacologic interventions aimed specifically at groups at high risk for uterine cancer due to endogenous hormonal factors could be justified. More must be learned about the associations of risk for endometrial cancer and the quantitative levels of estrogens and other hormones and their relative proportions. Once these factors are known, women with PCOS, diabetes, morbid obesity, or other predisposing conditions could be evaluated for unfavorable hormone profiles and appropriately targeted for treatment.

Although a substantial amount has been learned about ovarian cancer risks, the prospects for meaningful preventive measures aimed at this tumor are probably worse than for other gynecologic malignancies. Although several ovarian cancer risk factors seem to indict ovulatory activity as a common pathway to increased risk, the mechanism by which this occurs is unknown. Even if some of the hypothesized mechanisms prove to be correct, it is unclear how reasonable any interventions may be. However, if the long-term effect of oral contraceptive use on ovarian cancer risk is similar to its short-term effect, a substantial decline in ovarian cancer rates should result from pill use patterns of the past 40 years. Another reason for the limited prospects for prevention is that for several risk factors (e.g., protection associated with hysterectomy) no credible mechanism has been suggested. The associations promising the greatest opportunities for preventive actions are several recently suggested dietary relationships, specifically, decreased risks with consumption of diets high in fruits and vegetables and certain micronutrients. However, these observations need to be replicated in additional studies. Because of the preventive implications, attempts at confirmation should have high priority.

For cervical cancer, uterine cancer, and ovarian cancers, much is known about the risk factors. However, less is known about the precise biologic mechanisms through which the known risk factors operate. There is substantial enthusiasm for current interdisciplinary studies that incorporate state of the art laboratory assays into robust epidemiologic research designs focused on answering these mechanistic questions. Even among some of the more conservative etiologists, there is a belief that the gynecologic oncologist may soon be able to intervene much earlier in the natural history of these diseases, and in some instances, engage in primary prevention.

Molecular Pathogenesis of Gynecologic Cancers

ANDREW BERCHUCK ■ DOUGLAS A. LEVINE ■ JOHN H. FARLEY ■
MICHAEL J. BIRRER

INTRODUCTION

An overview of the molecular pathogenesis of cancer is presented in the initial sections of this chapter. A more comprehensive discussion of this topic can be found in Part I of *DeVita Hellman and Rosenberg's Cancer: Principles and Practice of Oncology* (1). Genetic alterations involved in the development of gynecologic cancers are covered in more detail in the latter sections of this chapter.

The causes of human cancers are diverse, but malignant transformation is invariably caused by the development of genetic alterations that disrupt cell growth (Table 2.1). Several classes of genetic alterations are involved in carcinogenesis, including changes in the sequence of genes (mutations), gains (amplifications) or losses (deletions) in the number of copies of genes and rearrangement and translocation of genes from their normal chromosomal locations (2). These alterations lead to activation of genes that stimulate proliferation (oncogenes) and inactivation of genes that inhibit proliferation (tumor-suppressor genes). Disruption of DNA-repair systems also often occurs in the process of malignant transformation and may lead to accelerated accumulation of genetic alterations. Because repair of genetic damage inhibits carcinogenesis, DNA-repair genes are also considered tumor suppressors.

Most transforming mutations in oncogenes alter a single amino acid at specific codons that produce overactive protein products (e.g., *KRAS*, *BRAF*), and only one allele need be mutated. In contrast, inactivation of tumor suppressors (e.g., *RB1*, *BRCA1*) requires loss of both copies of the gene (two hits). Mutations in tumor suppressors occur throughout the gene, and are usually small insertions, deletions or base substitutions that result in truncated protein products. Loss of the second nonmutated allele generally occurs due to chromosomal deletion, leading to abrogation of tumor-suppressor activity.

Cancers may have many genetic alterations, but only a small fraction of these are “driver” mutations responsible for malignant transformation. The majority are “passenger” mutations that arise secondarily due to genetic instability. Although not involved in the initial monoclonal development of a cancer, passenger mutations may play a role in clonal evolution and progression of the malignant phenotype. This may alter proteases involved in invasion and metastasis and caspases that regulate cell death in response to therapy.

Changes in gene expression due to epigenetic alterations (DNA methylation and acetylation), aberrant gene splicing, noncoding microRNAs, and other mechanisms also contribute to the malignant phenotype, but sequential genetic alterations leading to outgrowth of a clonal population of cells is the major determinant of whether a cancer develops as well as the time

Table 2.1 Molecular Alterations in Cancer

Genetic changes

Mutations

Mutations in oncogenes change a single amino acid and lead to gain of activity that stimulates proliferation (e.g., *KRAS*). These mutations are dominant and not dependent on changes in the other copy of the gene.

Mutations in tumor-suppressor genes (e.g., *PTEN*) and DNA repair genes (e.g., *BRCA1*) generally are small base insertions/deletions or single base changes that cause stop codons. These lead to truncated protein products that are nonfunctional. Loss of tumor-suppressor activity is usually dependent on deletion of the other copy of the gene.

Driver mutations play a critical role in the process of malignant transformation

Passenger mutations occur due to generalized genomic instability. Although not involved in malignant transformation, they may contribute to cancer phenotypes (e.g., metastatic potential, response to therapy)

DNA copy number changes

Deletion of one or both copies of a tumor-suppressor gene due to genomic instability leads to loss of a gene product (e.g., *RB1*)

Gain of additional copies of an oncogene leads to increased activity (e.g., *HER-2/neu*)

Gene rearrangements and translocations

When a gene is moved from its normal location to another chromosomal location, its expression may be increased due to proximity to a gene promoter (e.g., *ALK* in lung cancer)

Aneuploidy

Aneuploidy with gain or loss of complete chromosomes is common in many cancers (e.g., high-grade serous ovarian cancer) and likely plays a role in their development and progression.

Other biological processes

Epigenetic alterations

Hypermethylation of CpG islands in the promoter regions of tumor-suppressor genes may lead to gene inactivation (e.g., *MLH1*).

Loss of promoter methylation in genes that stimulate proliferation may provide an oncogenic stimulus (e.g., *IGF2*).

Changes in acetylation of histone proteins that coat DNA may also play a role in carcinogenesis.

Aberrant gene splicing

Genes may have alternative splice forms that produce messenger RNAs and proteins that have altered activity.

MicroRNAs

These small noncoding RNAs can affect gene expression by binding to messenger RNAs and blocking their translation. Altered miRNA expression plays a role in the development and behavior of some cancers.

FIGURE 2.1. All cancers are genetic. "Hereditary" cancers differ from "sporadic" cancers by virtue of association with a predisposing mutation inherited through the germ line. In contrast, all of the mutations in sporadic cancers are acquired somatically.

required for its development and progression. The histopathologic progression through hyperplasia, dysplasia, *carcinoma in situ*, and invasive carcinoma, reflects the multistep, multigenic nature of malignant transformation. Cancers may arise through the accumulation of acquired (somatic) alterations or through the inheritance of an alteration in the germline followed by the acquisition of additional somatic alterations (Fig. 2.1). Hereditary cancers are discussed in detail in Chapter 3.

The techniques used to study genetic alterations have evolved dramatically. Advances in the 1980s and 1990s enabled the discovery of several genes that frequently play a role in the development of cancers, including the *KRAS* and *HER-2/neu* oncogenes and the *TP53* and *RB1* tumor-suppressor genes. It became apparent that the spectrum of driver alterations varies considerably between cancer types, and among cancers of the same type. More recently, powerful new technologies have enabled comprehensive genomic studies. The Human Genome Project was completed in 2004 and provided a road map of the entire genome, including the approximately 18,000 protein-encoding genes. The HapMap project then catalogued the millions of common single nucleotide polymorphisms (SNPs) in the genome that change a single base in the DNA sequence. More recently the 1000 Genomes Project has characterized rarer germline genetic variants. A road map of normal human genetic variation and the development of faster and cheaper "next generation" DNA sequencing has allowed mutational analysis of complete cancer genomes. It has been shown that cancers typically have about 30 to 100 acquired mutations. However, cancers are continually evolving due to genetic instability and contain subclones that differ with respect to their mutational profile. A small number of genes are mutated in a high fraction of cancers (e.g., *KRAS*, *TP53*) likely reflecting the strong selective advantage these alterations confer. A much larger number of genes are mutated at considerably lower frequencies. The terms "mountains" and "hills" have been used to describe genes that are commonly versus rarely mutated. Mutations in cancers typically target multiple biological pathways (3). Several genes in a pathway may be mutated, but driver mutations in a pathway often are mutually exclusive when they involve the same pathway (e.g., *KRAS* and *BRAF*).

The Cancer Genome Atlas (TCGA) Project sponsored by the National Cancer Institute is performing a comprehensive genomic characterization of all common forms of human cancer. Ovarian and endometrial cancers were among the first to be studied by

TCGA and these findings have been incorporated into this chapter. The International Cancer Genome Consortium (ICGC) is performing similar genomic analyses of human cancers. Both TCGA and ICGC are depositing their data online in the public domain to stimulate further research. The full spectrum and complexity of the genomic alterations in a single cancer can be best captured in a Circos plot (Fig. 2.2), which uses a circular ideogram layout to facilitate the display of changes across the genome.

An understanding of the molecular pathogenesis of cancer provides the opportunity to better define subgroups within a given type of cancer that may differ with respect to clinical behavior or outcome. In addition, the identification of specific mutations has facilitated the development of therapies that target these alterations (4,5). In this regard, monoclonal antibodies and small molecules targeting aberrantly expressed cellular proteins that drive malignant growth have been successful in treating some cancers (e.g., trastuzumab targets *HER-2/neu* in breast cancer, gefitinib, and erlotinib target EGFR in lung and other cancers). However, resistance to therapy often occurs due to mutational heterogeneity both within the primary tumor and in metastases as clonal evolution develops over time. Unfortunately, many cancers, including most gynecologic cancers, have not proven easily amenable to targeted therapy, perhaps because their growth is not driven by a single altered gene or pathway. Successful therapy may require the use of multiple agents that target more than one gene or pathway.

In several types of common cancers, analysis of known "druggable" molecular targets has become part of the standard of care. Companion molecular diagnostic tests are often requisite to guide selective use of expensive targeted agents in patients most likely to benefit. As the cost of genomic analyses of cancers continues to fall, it will be increasingly feasible to perform full sequencing of cancers to look for less commonly mutated targets. This has the potential to facilitate even greater individualization of therapy based on the unique profile of alterations in a cancer, but the utility of this approach remains unproven.

Finally, an increased understanding of the molecular pathogenesis provides the opportunity to explore new approaches to early detection and prevention. This has been realized for cervical cancer with the identification of the human papilloma virus leading to creation of a vaccine. In ovarian and endometrial cancers, genetic changes that occur early in the development of cancers have the potential to serve as biomarkers for early detection and as surrogate endpoints in prevention studies.

FIGURE 2.2. Circos plot of somatic mutations in COLO-829. Chromosome ideograms are shown around the outer ring and are oriented pter–qter in a clockwise direction with centromeres indicated in red. Other tracks contain somatic alterations (from outside to inside): validated insertions (light green rectangles); validated deletions (dark green rectangles); heterozygous (light orange bars), and homozygous (dark orange bars) substitutions shown by density per 10 megabases; coding substitutions (colored squares: silent in gray, missense in purple, nonsense in red, and splice site in black); copy number (blue lines); regions of loss of heterozygosity (LOH) (red lines); validated intrachromosomal rearrangements (green lines); validated interchromosomal rearrangements (purple lines).

CELLULAR GROWTH AND DEATH

Proliferation

The number of cells in normal tissues is tightly regulated by a balance between cellular proliferation and death. The final common pathway for cell division involves distinct molecular switches that control cell cycle progression from G1 to the S phase of DNA synthesis (6). These include the Rb and E2F proteins and their various regulatory cyclins, cyclin dependent kinases (cdks) and cdk inhibitors. The events that facilitate progression from G2 to mitosis and cell division are regulated by other cyclins and cdks (Fig. 2.3), as well as by molecules involved in chromosomal segregation such as microtubules. When the chromosomes do not separate properly, aneuploidy may occur

with gain or loss of complete chromosomes (7). Aneuploidy is a hallmark of many cancers and likely plays a role in their development and progression.

Cell cycle progression is also dependent on ubiquitin-mediated proteolysis of molecules involved in cell cycle arrest (6). Ubiquitin is a 76 amino acid polypeptide that can be linked to lysine residues of proteins, and ubiquitination marks proteins for proteolysis and destruction by the proteasome complex. Proteasome inhibitors have been successfully employed to treat some hematologic malignancies, and the *FBXW7* (*CDC4*) ubiquitin ligase has been shown to be mutated in some serous uterine cancers.

In some tissues—such as the bone marrow, epidermis, and gastrointestinal tract—the life span of mature cells is relatively short and high rates of proliferation are required to maintain the population; while in other tissues—such as liver, muscle

FIGURE 2.3. Molecular control of cell-cycle progression. A linear version of the various stages of the cell cycle is shown with the various cyclin/cyclin-dependent kinase complexes corresponding to the stages that they control.

and brain—cells are long lived and proliferation rarely occurs. Complex molecular mechanisms have evolved to closely regulate proliferation. These involve a finely tuned balance between growth stimulatory and inhibitory signals.

Increased proliferation is one of the hallmarks of cancer. There may be increased activity of genes involved in stimulating proliferation (oncogenes) and/or loss of growth-inhibitory (tumor-suppressor) genes. In the past, it was thought that cancer might arise solely because of more rapid proliferation or a higher fraction of cells proliferating. It is now clear that this was an overly simplistic view. Although increased proliferation is a characteristic of many cancers, the fraction of cancer cells actively dividing and the time required to transit the cell cycle is not always strikingly increased. Altered regulation of proliferation is only one of several factors that contribute to malignant transformation.

Cell death

In addition to being driven by increased proliferation, growth of a cancer may be attributable to cellular resistance to death. At least three distinct types of cell death pathways have been characterized, including apoptosis, autophagy, and necrosis (8).

Apoptosis

The term “apoptosis” derives from Greek and alludes to a process akin to leaves dying and falling off a tree. Apoptosis is an active energy-dependent process that involves cleavage of the DNA by endonucleases and proteins by proteases called caspases. Morphologically, apoptosis is characterized by condensation of chromatin, nuclear and cytoplasmic blebbing, and cellular shrinkage. The molecular events that effect apoptosis in response to various stimuli are complex and have only been partially elucidated, but several reliable markers of apoptosis have been discovered including annexin V, caspase-3 activation, and DNA fragmentation.

External stimuli such as TNF, TRAIL, Fas and other death ligands that interact with cell surface receptors can induce

activation of caspases and lead to apoptosis via the extrinsic pathway. The intrinsic apoptosis pathway is activated in response to a wide range of stresses including DNA damage and deprivation of growth factors. The intrinsic apoptosis pathway is regulated by a complex interaction of pro- and antiapoptotic proteins in the mitochondrial membrane that affect its permeability. Proteins that increase permeability allow release of cytochrome *c*, which activates the apoptosome complex leading to activation of caspases that effect apoptosis. Conversely, proteins that stabilize mitochondrial membranes inhibit apoptosis. The first major insight that led to the understanding of the intrinsic apoptosis pathway was the finding that an activating translocation of the *BCL-2* gene in B-cell lymphomas results in essentially complete inhibition of apoptosis (9). Subsequent studies demonstrated that the antiapoptotic effect of *BCL-2* is attributable to stabilization of the mitochondrial membrane. Additional genes related to *BCL-2*, such as *BAD*, *BCL-XL* and others, also block apoptosis by inhibiting membrane permeability. Other genes in the *BCL* family, such as *BAX* and *BAK*, increase membrane permeability and are pro-apoptotic. An understanding of the complex system of checks and balances involved in regulation of apoptosis provides opportunities for the development of targeted therapies (10).

In addition to restraining the number of cells in a population, apoptosis serves an important role in preventing malignant transformation by allowing for elimination of cells that have undergone genetic damage. Following exposure of cells to mutagenic stimuli, including radiation and carcinogenic drugs, the cell cycle is arrested so that DNA damage may be repaired. If DNA repair is not sufficient, apoptosis occurs so that damaged cells do not survive. This serves as an anticancer surveillance mechanism by which mutated cells are eliminated before they become fully transformed. The *TP53* tumor-suppressor gene is a critical regulator of cell cycle arrest and apoptosis in response to DNA damage. Many of the molecules involved in apoptosis reside in the mitochondria and are encoded by mitochondrial DNA. Mutations in mitochondrial DNA have been shown to be frequent in cancer and may play a role in evasion of apoptosis (11).

Necrosis

Necrosis is a type of cell death that is distinct from apoptosis and is the result of bioenergetic compromise (12). Morphologic changes include swollen organelles and rupture of the cell membrane leading to loss of osmoregulation and cellular fragmentation. Necrosis is a less well-regulated process that leads to spillage of protein contents and this may incite a brisk immune response. This is in contrast to the silent elimination of cells by apoptosis, which typically elicits a minimal immune response. There is evidence that some drugs may enhance necrotic death in tumors and this may stimulate a beneficial antitumor immune response.

Autophagy

Autophagy is a potentially reversible process in which a cell that is stressed “eats” itself (13). A wide range of stresses have been identified that may elicit autophagy (some of which may also elicit apoptosis), including growth factor deprivation and accumulation of reactive oxygen species. Unlike necrosis and apoptosis, in which loss of integrity of the cytoplasmic and nuclear membranes respectively are defining events, autophagy is characterized by the formation of cytoplasmic autophagic vesicles into which cellular proteins and organelles are sequestered. This may allow for cell survival if damaged organelles can be repaired. Conversely, the process may lead to cell death if these vesicles fuse with lysosomes with resultant degradation of their contents. Several cancer therapeutic agents have been shown to induce autophagy, while targeted disruption of genes such as *ATG5* that are involved in autophagy can inhibit cell death.

Cellular Senescence

Normal cells are only capable of undergoing division a finite number of times before becoming senescent and this represents a barrier to immortality (14). Senescence can also be triggered by stresses such as oncogene activation. Induction of senescence is mediated by persistent p16 and p53 activation leading to permanent cell cycle arrest. Cellular senescence is regulated by a biological clock related to progressive shortening of repetitive DNA sequences (TTAGGG) called telomeres that cap the ends of chromosomes. Telomeres are involved in chromosome stabilization and in preventing recombination and chromosomal translocations and aneuploidy during mitosis (15). At birth, chromosomes have long telomeric sequences (150,000 bases) that become progressively shorter by 50 to 200 bases each time a cell divides. Telomerase is a ribonucleoprotein complex. The RNA component serves as a template for telomere extension and the protein subunit acts to catalyze the synthesis of new telomeric repeats.

Replicative senescence serves as a defense against immortalization and malignant transformation by placing limits on proliferation of cells that have accumulated genetic damage. Reactivation of telomerase is critical to the emergence of cancers (16), but early in the process of malignant transformation telomere shortening and dysfunction may promote the carcinogenic process through the generation of chromosomal rearrangements and aneuploidy (17). Progressive telomere shortening during adulthood may explain the association between advancing age and increased cancer risk, particularly for epithelial malignancies. This risk has been mainly attributed to progressive accumulation of mutations with aging, but this theory does not explain the marked aneuploidy of most epithelial cancers.

Telomerase activity is present in a high fraction of many cancers, including ovarian (18), cervical (19) and endometrial cancers (20). It has been suggested that detection of telomerase might be useful for early diagnosis of cancer, but lack of specificity is a significant issue. In this regard, endometrium is one of

the normal adult tissues in which telomerase expression is most common (21). Perhaps this relates to the need for a large number of lifetime cell divisions because of rapid growth and shedding of this tissue each month during the reproductive years. Therapeutic approaches to inhibiting telomerase are under development that would reverse their immortalized state and render them susceptible again to normal replicative senescence (22).

Stem Cells

Stem cells in normal tissues have the capacity to undergo asymmetric division to produce daughter cells that undergo differentiation and eventually senescence, and can self-renew to produce more stem cells (23). Stem cells have been most easily identifiable in tissues that normally are highly proliferative, such as the bone marrow, skin and intestine, in which a constant stream of cells are being born to replace those that are differentiating and dying. It has been theorized that stem cells may exist in cancers and that these have the capacity for self-renewal and differentiation into populations of cells that recapitulate tumor heterogeneity (24). Stem cells are also referred to as tumorigenic cells because of their capacity to regenerate tumors. The stem cell theory suggests that less than 1% of cells in a cancer are stem cells and that by virtue of being dormant or quiescent, they may be relatively resistant to chemotherapy and radiation. It is postulated that cancer stem cells may persist as microscopic disease after eradication of most cancer cells and give rise to recurrent disease. There has been a great deal of interest in identifying and characterizing cancer stem cells, as this could facilitate development of therapies that specifically target these resistant cells.

Several molecular markers have been identified that define cancer stem cells (25), including the cell membrane glycoprotein CD133 (Prominin). Expression of CD133 has been associated with greater proliferative potential and ability to form tumors in animal models. CD44 is the receptor for hyaluronic acid and has been identified as a stem cell marker in several cancer types. CD117, also known as c-kit, is another well-characterized stem cell marker that has been implicated in several solid tumors (25). CD24 is a mucin-like cell surface glycoprotein marker that has been identified as a stem cell marker. The Sonic Hedgehog and WNT pathways also have been implicated in stem cell behavior.

Although expression of the markers and pathways described above in cancers have been associated with stem cell characteristics, the existence of discrete cancer stem cell populations has not been definitively proven. It is possible that the genes and pathways involved in cellular renewal are simply more highly expressed in a fraction of cells within heterogeneous tumors (26). Cancer stem cells may exist in some malignancies but not others. In this regard, demonstration of progenitor stem cells has been more robust in leukemias than in solid tumors.

ORIGINS OF GENETIC ALTERATIONS

Human cancers arise due to a series of genetic alterations that lead to disruption of normal mechanisms that govern cell growth, death, and senescence (2). Genetic damage may be inherited or arise after birth due to various exposures including those related to carcinogenic substances such as tobacco and asbestos, physical factors such as ultraviolet radiation, infections such as HPV, dietary factors, obesity, and inflammation. However much of the acquired genetic damage that causes cancer is due to endogenous mutagenic processes within the cell (Table 2.2). The incidence of most cancers increases with aging because the longer a person is alive the higher the likelihood of a cell acquiring sufficient damage to become fully transformed. It is thought that at least three to six alterations are required to

Table 2.2 Origins of Genetic Damage in Human Cancers

Type of genetic damage	Examples
<i>Germline alterations</i>	
High-penetrance genes	<i>BRCA1</i> , <i>BRCA2</i> (breast, ovarian cancers) <i>MLH1</i> , <i>MSH2</i> (Lynch syndrome)
Low-penetrance genes	SNPs associated with various cancers
<i>Exogenous carcinogens</i>	
Ultraviolet radiation	<i>TP53</i> mutations in skin cancers
Tobacco	<i>TP53</i> mutations in lung cancers
Viruses	HPV inactivation of <i>RB</i> and <i>TP53</i> in cervical cancers
<i>Endogenous DNA damage</i>	
Cytosine methylation and deamination	<i>TP53</i> mutations in many cancer types
DNA Hydrolysis	various genes
Spontaneous errors in DNA synthesis	various genes
Free radical production due to oxidative stress	various genes

fully transform a cell. Many cancers are genetically unstable and this leads to accumulation of a substantial number of secondary changes and the development of subclones that play a role in evolution of the malignant phenotype.

Inherited Cancer Susceptibility

Although most cancers arise sporadically due to acquired genetic damage, inherited mutations in cancer susceptibility genes are responsible for some familial cases. The age of cancer onset is younger in these families and it is not unusual for some individuals to be affected with multiple primary cancers. Tumor-suppressor genes and DNA repair genes have been implicated most frequently in hereditary cancer syndromes. The most common forms of hereditary cancer syndromes predispose to breast/ovarian (*BRCA1/2* genes) and colon/endometrial (DNA mismatch repair genes) cancers. Although affected individuals carry the germline alteration in every cell of their bodies, paradoxically, cancer susceptibility genes are characterized by a limited repertoire of cancers. The penetrance of cancer susceptibility genes is incomplete, as all individuals who inherit a mutation do not develop cancer. The emergence of cancers is dependent on the occurrence of additional genetic alterations. Hereditary cancer syndromes are covered in detail in Chapter 3.

In addition to the high-penetrance mutations noted above that cause familial cancer syndromes, low-penetrance genetic variants may also affect cancer susceptibility, albeit less dramatically (27). There are over 10 million polymorphic genetic loci in the human genome, most of which are SNPs (e.g., CCA to CAA). Many of these SNPs are common, with the rarer of the two alleles occurring in more than 5% of individuals. Genome wide association studies have discovered a number of SNPs that affect the risk of ovarian cancer by 10% to 20% per rare allele copy (27). A more complete understanding of the genetic factors that affect cancer susceptibility could facilitate implementation of screening and prevention approaches in subsets of the population at increased risk.

Acquired Genetic Damage

The etiology of acquired genetic damage in cancers also has been elucidated to some extent. For example, a strong causal link exists between cigarette smoke and cancers of the aerodigestive tract, between ultraviolet radiation and skin cancer, and between HPV and lower genital tract cancers (Table 2.2). For many common forms of cancer (e.g., colon, breast, prostate, endometrium, ovary), there is not a strong association with specific carcinogens. It is thought that the genetic alterations responsible for these cancers may arise mainly due to endogenous mutagenic processes. This includes methylation and deamination of cytosine residues leading to transition mutations to thymidine. In this regard, in most types of cancers that are not associated with a specific carcinogen, transition mutations from purine to purine or pyrimidine to pyrimidine are much more common than transversion mutations that change purine to pyrimidine or pyrimidine to purine. An additional mechanism of endogenous damage includes spontaneous errors in DNA synthesis that frequently occur during the process of DNA replication associated with normal proliferation. Free radicals generated in response to inflammation and other cellular damage may also cause DNA damage. These endogenous processes are thought to produce mutations on an ongoing basis. Several networks of highly effective DNA damage surveillance and repair genes exist, but some mutations may elude them. The efficiency of these DNA damage response systems varies between individuals due to genetic and other factors and may affect susceptibility to cancer.

Epigenetic Changes

Epigenetics comprises heritable changes that are not due to alterations in DNA sequence (28,29). Methylation of cytosine residues that reside next to guanine residues (CpG dinucleotides) is the primary mechanism of epigenetic regulation, and this process is regulated by a family of DNA methyltransferases. CpG dinucleotides are asymmetrically distributed with about half of human genes containing CpG-rich regions termed “CpG islands” at their transcriptional start sites. Most genes are regulated without changing the methylation status of the CpG sites, but permanent silencing of genes associated with X-chromosome inactivation and genomic imprinting is due to heritable methylation of CpG islands.

Most cancers have globally reduced DNA methylation, which may lead to activation of some genes. Conversely, selective hypermethylation of CpG islands in the promoter regions of tumor-suppressor genes may lead to gene inactivation (e.g., *BRCA1*, *MLH1*). In addition, loss of silencing of imprinted genes that stimulate proliferation, such as *IGF2*, may provide an oncogenic stimulus. Acetylation and methylation of the histone proteins that coat DNA represent another level of epigenetic regulation that is altered in cancer. The underlying cause of epigenetic alterations in cancer remains poorly understood.

Alterations in Signal Transduction Pathways in Malignant Transformation

Alterations in genes that stimulate cellular growth (oncogenes) can cause malignant transformation when they become overactive (2). In some cancers, amplification of oncogenes occurs with resultant overexpression of the corresponding protein. Instead of two copies of one of these genes, there may be many additional copies. Some oncogenes may become overactive when affected by gain of function point mutations. Finally, oncogenes may be translocated from one chromosomal location to another and come under the influence of gene promoters that cause overexpression. This latter mechanism frequently occurs as a driving

event in the development of leukemias and lymphomas, but is infrequent in gynecologic cancers. However, some other types of solid tumors may have translocations that represent significant driver events, such as those involving the *ALK* receptor gene in lung cancer. These have been targeted successfully with the monoclonal antibody crizotinib (30).

Loss of tumor-suppressor gene function also plays a role in the development of most cancers. This usually involves a two-step process in which both copies of a tumor-suppressor gene are inactivated. This often involves mutation of one copy of a tumor-suppressor gene and loss of the other copy due to deletion of a segment of the chromosome where the gene resides (e.g., *RB1*). There is also evidence that some tumor-suppressor genes may be inactivated due to methylation of the promoter region of the gene (e.g., *MLH1*, *BRCA1*). The promoter is an area proximal to the coding sequence that binds transcription factors that regulate whether or not the gene is transcribed from DNA into RNA. When the promoter is methylated, it is resistant to activation and the gene is essentially silenced despite remaining structurally intact. This two-hit paradigm of tumor-suppressor gene inactivation is relevant to both hereditary cancer syndromes, in which one mutation is inherited and the second acquired, and to sporadic cancers, in which both hits are acquired. Tumor-suppressor gene products are found throughout the cell, reflecting their diverse functions.

The sections below will review the role of oncogenes and tumor-suppressor genes in signal transduction pathways that regulate cellular growth and metabolism (3). These pathways are complex and have considerable overlap and redundancy (31), and an exhaustive discussion is beyond the scope of this book. Pathways for which there is less evidence of a role in driving the development of gynecologic cancers, such as the Hedgehog, Notch, and cytokine pathways, are not covered.

Peptide Growth Factors and Receptor Tyrosine Kinases

Peptide growth factors in the extracellular space, such as those of the EGF, PDGF, and FGF families, stimulate a cascade of molecular events that leads to proliferation by binding to high affinity cell membrane receptors (Fig. 2.4). Growth factors are involved in normal cellular processes such as stromal-epithelial communication, tissue regeneration, and wound healing. The concept that

autocrine growth stimulation might be a key strategy by which cancer cell proliferation becomes autonomous has received considerable attention. In this model, it is postulated that cancers secrete stimulatory growth factors that then interact with receptors on the same cell. Although peptide growth factors provide a growth stimulatory signal, there is little evidence to suggest that overproduction of growth factors is a precipitating event in the development of most cancers. Increased expression of peptide growth factors likely facilitates, rather than drives, malignant transformation.

Cell membrane receptors that bind peptide growth factors are composed of an extracellular ligand binding domain, a membrane-spanning region, and a cytoplasmic tyrosine kinase domain (31,32). Binding of a growth factor to the extracellular domain results in dimerization and conformational shifts in the receptors and activation of the inner tyrosine kinase. The kinase transfers a phosphate group from ATP to specific tyrosine residues both on the growth factor receptor itself (autophosphorylation) and on molecular targets in the cell interior leading to activation of secondary signals that stimulate proliferation. Growth of some cancers is driven by overexpression of receptor tyrosine kinases. The epidermal growth factor receptor (EGFR) family of receptor tyrosine kinases plays a significant role in the development of several types of cancers, and includes ErbB-1 (EGFR), ErbB-2 (*HER-2/neu*), ErbB-3, and ErbB-4. These receptors are activated by binding of ligands, including EGF, transforming growth factor- α , amphiregulin, and the neuregulins.

Because receptor tyrosine kinases are located on the cell surface, they are appealing therapeutic targets. A number of agents that target the EGFR family have been developed and translated into clinical practice. Trastuzumab is a monoclonal antibody that binds to *HER-2/neu*, and it is widely used in the treatment of breast cancers that overexpress this receptor (33). Cetuximab is a monoclonal antibody that targets the extracellular domain of EGFR, whereas gefitinib is a direct inhibitor of the EGFR tyrosine kinase (34). Lapatinib is a dual EGFR/HER-2 kinase inhibitor. Likewise, therapeutic approaches have been developed that target other receptor tyrosine kinases. Imatinib antagonizes the activity of the BCR-ABL, c-kit, and platelet-derived growth factor (PDGF) receptor tyrosine kinases and has proven highly effective in treatment of chronic myelogenous leukemias and gastrointestinal stromal tumors.

FIGURE 2.4. Receptor tyrosine kinase pathway. Most receptor tyrosine kinases stimulate the activity of the Ras guanine nucleotide exchange factor son of sevenless (SOS), which associates with the linker proteins Shc and Grb2. The activation of Ras by SOS stimulates a protein serine kinase cascade initiated by Raf, which stimulates MEK. MEK then activates the extracellular signaling-regulated kinases (ERKs). ERKs phosphorylate transcription factors to regulate gene expression.

Nonreceptor Kinases and Phosphatases

Following interaction of growth factors with cell membrane receptors, secondary molecular signals are generated to transmit the growth stimulus to the nucleus. This function is served by a multitude of complex and overlapping signal transduction pathways that occur in the inner cell membrane and cytoplasm. Many of these signals involve phosphorylation of proteins by enzymes known as nonreceptor kinases. The kinases that are involved in growth regulation are of two types, those that phosphorylate tyrosine residues of target proteins, including those of the *SRC* family (35), and others that are specific for serine and/or threonine residues such as *AKT* (36). The activity of kinases is opposed by phosphatases such as *PTEN*, which act in opposition to the kinases by removing phosphates from the target proteins. The *PTEN* gene is among the most frequently mutated tumor-suppressor genes in human cancers.

RAS/RAF, Mitogen-Activated Protein Kinase (MAPK) Pathway

Guanosine-triphosphate-binding proteins (G proteins) such as RAS represent another class of molecules involved in transmission of growth signals (Figs. 2.4 and 2.5A). They are located on

the inner aspect of the cell membrane and are positively regulated by Grb and SOS in response to receptor tyrosine kinases and other signals. They have intrinsic GTPase activity that catalyzes the exchange of GTP (guanine-tri-phosphate) for GDP (guanine-di-phosphate). In their active GTP bound form, G proteins interact with kinases that are involved in relaying the mitogenic signal, such as those of the MAP kinase family. Conversely, hydrolysis of GTP to GDP, which is stimulated by GTPase activating proteins (GAPs), leads to inactivation of G proteins. The RAS family of G proteins is among the most frequently mutated oncogenes in human cancers. Activation of RAS genes usually involves point mutations in codons 12, 13, or 61 that result in constitutively activated molecules (37).

The RAF family of genes encode serine-threonine kinases that interact with RAS proteins and propagate signaling by

activating MAP kinases (MEK) which translocate to the nucleus. Mutations in the *BRAF* gene occur in many cancers that lack RAS mutations and most of these mutations involve codon 599 in the kinase domain (38). The mutual exclusivity of *KRAS* and *BRAF* mutations is consistent with the need to only activate one gene in a pathway. Melanomas often have mutations in codon 600 of *BRAF*. The *BRAF* kinase inhibitor vemurafenib has been shown to be highly active in melanomas with the *BRAF* V600E mutation (39).

The RAF serine/threonine kinase is downstream of RAS, and its activation leads to signaling via mitogen-activated protein kinase kinase (MAPKK), also called MEK, which activates mitogen-activated protein (MAP) kinase or extracellular regulated kinase (ERK). MAP kinase activation results in phosphorylation and activation of nuclear factors such as ribosomal S6 kinase

FIGURE 2.5. A: The ras/raf/MEK/MAPK pathway is activated by multiple growth factor receptors (here exemplified by ErbB1 and ErbB2) as well as several intracellular tyrosine kinases such as SRC and ABL. Activated RAS stimulates a sequence of phosphorylation events mediated by RAF, MEK, and ERK (MAP) kinases. Activated MAP kinase (MAPK) translocates to the nucleus and activates proteins such as MYC, JUN, and FOS that promote the transcription of numerous genes involved in tumor growth. **B:** The phosphatidylinositol 3-kinase (PI3K) pathway is activated by RAS and by a number of growth factor receptors (here exemplified IGF1R and the ErbB1/ErbB2 heterodimer). Activated PI3K generates phosphatidylinositol-3,4,5-triphosphate (PIP3), which activates phosphoinositide-dependent kinase-1 (PDK). In turn, PDK phosphorylates AKT. PTEN is an endogenous inhibitor of AKT activation. Phosphorylated AKT transduces multiple downstream signals, including activation of the mTOR and inhibition of the FOXO family of transcription factors. mTOR activation promotes the synthesis of proteins required for cell growth and cell cycle progression.

and transcription factors *JUN*, *MYC* and *FOS*, resulting in the switching on of a number of genes associated with proliferation.

PI3K/AKT/mTOR Pathway

Phosphatidylinositol 3-kinases (PI3Ks) are a class of lipid kinases that phosphorylate phosphoinositides (PIs) at the position D3 of the inositol ring (40). Extracellular molecules such as growth factors are the main effectors for PI3K pathway activation through the interaction with receptor tyrosine kinases and G protein-coupled receptors (Fig. 2.5B). Phosphorylated PIs serve as plasma docking sites for the recruitment of pleckstrin-homology domain containing proteins such as AKT and its upstream activator PDK1. PI3K activation is one of the main causes of increased proliferation and resistance to apoptosis. The *PIK3CA* gene is one of the most frequently mutated oncogenes in human cancers.

Alterations in PI3Ks and downstream effectors, including AKT and mTOR, frequently are involved in initiation and maintenance of the tumorigenic phenotype. The PI3K-AKT pathway promotes cell growth and survival and inhibits apoptosis and autophagy through several mechanisms. AKT activates the mammalian target of rapamycin (mTOR) pathway (Fig. 2.5B) and modulates genes that inhibit cell cycle progression (e.g., *cdks*, *CHK1*, and *MDM2*). AKT targets include the pro-apoptotic effectors *BAD* and *BAX*, which are inhibited by phosphorylation respectively at Ser136 and Ser184, resulting in inhibition of the apoptotic response. AKT also inhibits the expression of BH3-only proteins such as *BAD* and *BIM* through effects on transcription factors, such as Forkhead family proteins (e.g., *FOXO3a*) and *p53*. AKT also influences *p53* activity through *MDM2* phosphorylation at Ser166 and Ser186, which promotes its translocation to the nucleus, with subsequent destabilization. AKT can phosphorylate and activate I κ B kinase- α , which in turn phosphorylates I κ B, targeting it for degradation. This leads to nuclear translocation and activation of the transcription factor NF- κ B and transcription of NF- κ B-dependent pro-survival genes.

The *PTEN* tumor suppressor is the most important negative regulator of the PI3K signaling pathway (41). It is a lipid and protein phosphatase that removes phosphates in opposition to PI3K tyrosine kinases. Its ability to dephosphorylate phosphatidylinositol 3,4,5-trisphosphate (PIP3) resulting in phosphatidylinositol 4,5-bisphosphate (PIP2) inhibits oncogenic PI3K-dependent signaling. Although *PTEN* is a tumor suppressor and may be completely lost due to mutation and deletion of the two copies of the gene, mutational inactivation of one copy of the gene (haploinsufficiency) also appears to facilitate malignant transformation.

Both genetic and epigenetic alterations affect the activity of this pathway (40). Mutations in the *PIK3CA* gene that lead to increased activity frequently occur in human cancers, including ovarian and endometrial cancers. *PTEN* is frequently targeted by either germline or somatic mutation, and is the second most frequently mutated gene in human cancers. In addition, loss of heterozygosity or promoter hypermethylation occurs in a broad range of cancers including endometrioid ovarian and endometrial cancers. Inhibition of the PI3K/Akt/mTOR pathway represents an attractive therapeutic approach (42).

WNT Pathway

β -catenin (*CTNNB1*) is involved along with cadherins in cell-cell adhesion junctions and may play a role in inhibition of excessive growth when cells come in contact with each other. β -catenin also may be translocated to the nucleus and play a role in regulating transcription of genes involved in embryonic

FIGURE 2.6. Wingless (WNT)/ β -catenin signaling. WNT extracellular ligands bind Frizzled receptors and regulate the phosphorylation status of axin. Axin functions as part of the destruction complex that regulates the stability of β -catenin, a transcriptional regulator.

development, cell differentiation, and cell polarity (Fig. 2.6). β -catenin activity is regulated by the WNT pathway (31). The WNT family of genes encodes secreted peptides that interact with Frizzled family cell surface receptors. Frizzled activates the intracellular Dishevelled protein resulting in an increase in the amount of β -catenin translocated to the nucleus. Dishevelled accomplishes this by inhibiting a complex of proteins that includes axin, GSK-3 β , and APC that normally promote proteolytic degradation of β -catenin. This allows β -catenin to enter the nucleus and interact with TCF/LEF family transcription factors to promote gene expression.

Genes encoding WNT signaling inhibitors are often down-regulated during carcinogenesis and driver mutations in several of these genes (*APC*, *Axin*, *GSK-3 β* , *β -catenin*) occur frequently in human cancers, including endometrial cancers. Germline mutations in the *APC* gene are responsible for familial adenomatous polyposis of the colon.

Nuclear Oncogenes

If proliferation is to occur in response to signals generated in the cell membrane and cytoplasm, these events must lead to activation of nuclear transcription factors and other gene products responsible for stimulating DNA replication and cell division (Fig. 2.5A). Expression of several genes that encode nuclear proteins increases dramatically within minutes of treatment of cells with peptide growth factors. Once induced, the products of these genes bind to specific DNA regulatory elements and induce transcription of genes involved in DNA synthesis and cell division. Examples include the *FOS* and *JUN* genes, which dimerize to form the AP1 transcription complex. When inappropriately overexpressed these transcription factors can act as oncogenes. The *MYC* family of nuclear transcription factors is often involved in the development of human cancers, including some ovarian cancers, due to amplification/overexpression. Many of the nuclear regulatory genes such as *MYC* that control proliferation also impact the threshold for apoptosis. Thus, there is overlap in the molecular pathways that regulate the opposing processes of proliferation and apoptosis.

Genes involved in chromatin remodeling also that have been implicated as oncogenes (e.g., ARID1A). Finally, genes that positively regulate cell cycle progression may be amplified and/or overexpressed in some cancers leading to unrestrained proliferation (e.g., cyclin D1 [CCND1] and cyclin E1 [CCNE1]).

Nuclear Tumor-Suppressor Genes

The retinoblastoma gene (*RB*) was the first tumor-suppressor gene discovered and is frequently mutated in human cancers (43,44). It was named based on its discovery in the context of a rare hereditary cancer syndrome, as have many other tumor-suppressor genes. The *RB* gene plays a key role in regulation of cell cycle progression. In the G1 phase of the cell cycle RB protein binds to the E2F family of transcription factors and prevents it from activating transcription of other genes involved in DNA replication and cell cycle progression. This serves as an important restriction point that can protect genomic integrity if DNA damage is present. G1 arrest is maintained by cyclin dependent kinase (cdk) inhibitors such as p16, p21, and p27 that prevent phosphorylation of RB (45). When RB is phosphorylated by cyclin/cdk complexes, E2F is released and stimulates entry into the DNA synthesis phase of the cell cycle. Other cyclins and cyclin dependent kinases are involved in progression from G2 to mitosis. Mutations in the *RB* gene have been noted primarily in retinoblastomas and sarcomas, but less frequently in other types of cancers. By maintaining G1 arrest, the cdk inhibitors p16, p21, p27, and others act as tumor-suppressor genes. Loss of p16 (*CDKN2A*) tumor-suppressor function due to genomic deletion or promoter methylation occurs in some cancers. Likewise, loss of p21 and p27 has been noted in some cancers as well.

Mutation of the *TP53* tumor-suppressor gene is the most frequent genetic event described thus far in human cancers (46,47). The *TP53* gene encodes a 393 amino acid protein that plays a central role in the regulation of both proliferation and apoptosis. In normal cells, p53 protein resides in the nucleus and exerts its tumor-suppressor activity by binding to transcriptional regulatory elements of genes, such as the cdk inhibitor p21, that act to arrest cells in G1. The *MDM2* gene product degrades p53 protein when appropriate, whereas p14ARF down-regulates *MDM2* when up-regulation of p53 is needed to initiate cell cycle arrest.

Many cancers have missense mutations in one copy of the *TP53* gene that result in substitution of a single amino acid in exons 5 through 8, which encode the DNA binding domains that are involved in regulating transcription (Fig. 2.7). Although these mutant *TP53* genes encode full-length proteins, they are unable to bind to DNA and regulate transcription of other genes. Mutation of one copy of the *TP53* gene often is accompanied by deletion of the other copy, leaving the cancer cell with only mutant p53 protein. If the cancer cell retains one normal copy of the *TP53* gene, mutant p53 protein can complex with

wild-type p53 protein and prevent it from oligomerizing and interacting with DNA. Because inactivation of both *TP53* alleles is not required for loss of p53 function, mutant p53 is said to act in a “dominant negative” fashion. While normal cells have low levels of p53 protein because it is rapidly degraded, missense mutations encode protein products that are resistant to degradation. The resultant overaccumulation of mutant p53 protein in the nucleus can be detected immunohistochemically. A smaller fraction of cancers have mutations in the *TP53* gene that encode truncated protein products. In these cases, loss of the other allele occurs as the second event as is seen with other tumor-suppressor genes.

Beyond simply inhibiting proliferation, normal p53 is thought to play a role in preventing cancer by stimulating apoptosis of cells that have undergone excessive genetic damage. In this regard, p53 has been described as the “guardian of the genome” because it delays entry into S phase until the genome has been cleansed of mutations. If DNA repair is inadequate, p53 may initiate apoptosis, thereby eliminating cells with genetic damage (Junttila and Evan, 2009).

TGF- β Pathway

The transforming growth factor-beta (TGF- β) family of growth factors inhibits proliferation (48). It is thought that TGF- β causes G1 arrest by inducing expression of cyclin dependent kinase inhibitors such as p27. Three closely related forms of TGF- β have been discovered that are encoded by separate genes (*TGF- β 1*, *TGF- β 2*, *TGF- β 3*). TGF- β is secreted in an inactive form bound to a portion of its precursor molecule from which it must be cleaved to release biologically active TGF- β . Active TGF- β interacts with type I and type II cell surface TGF- β receptors and initiates serine/threonine kinase activity (49). Prominent intracellular targets include a class of molecules called SMADs that translocate to the nucleus upon TGF- β receptor mediated phosphorylation and act as transcriptional regulator. In the nucleus, the SMAD complex interacts with other DNA-binding transcription factors and co-factors to regulate the transcription of TGF- β target genes to initiate growth arrest. Typical events include the upregulation of cyclin-dependent kinase inhibitors (p16, p15, p21, and p27) and translation-inhibitory protein 4eBP1 as well as the down regulation of MYC. In addition to growth arrest, TGF- β also limits tumor progression through the induction of apoptosis.

MicroRNA

MicroRNAs (miRNA) consist of single RNA strands of about 21 to 23 nucleotides that do not encode proteins (Fig. 2.8). They bind to messenger RNAs that contain complementary sequences and can block protein translation. In addition to regulation of normal biological processes, dysregulation of miRNA

FIGURE 2.7. Inactivation of the p53 gene. **A:** Normal p53 protein binds to transcriptional regulatory elements in DNA. **B:** p53 missense mutations encode proteins that no longer bind to DNA and the mutant protein complexes with and inactivates any remaining normal p53 in the nucleus. **C:** p53 mutations that encode truncated protein products result in proteins that no longer bind to DNA, and these mutations usually are accompanied by deletion of the wild-type p53 allele.

FIGURE 2.8. MicroRNA pathways.

expression appears to play a role in the development and behavior of human cancers (50).

MiRNA production begins in the nucleus from several kilobase-long primary miRNAs (pri-miRNA). These pri-miRNAs undergo cleavage to produce short hairpin-shaped intermediates known as precursor miRNAs (pre-miRNA), which are approximately 70 nucleotides in length.

Drosha, a RNase III enzyme, along with the DiGeorge syndrome critical region gene 8 (DGCR8), processes the precursors prior to translocation to the cytoplasm via Exportin-5. Subsequently, pre-miRNAs are cleaved by Dicer, also an RNase III enzyme, resulting in mature miRNAs. SiRNA, an approximately 21-nucleotide single-stranded sequence, is derived within the cytoplasm and does not require processing by the Drosha-DGCR8 complex. Mature miRNAs and siRNAs are then activated through the RNA-induced silencing complex, which produces host mRNA degradation and/or translational repression upon binding to the target. High Dicer and Drosha expression have been shown to be associated with increased median survival in ovarian cancer (>11 years, vs. 2.7 years) (51).

Exogenous constructs of either siRNAs or short hairpin RNAs (shRNA) can also be introduced into cells through transfection. ShRNAs are introduced through viral vectors to produce stable gene silencing, whereas siRNA transfections are more transient. RNAi technology has been used as a research tool to study the effect of turning off various genes and also potentially has therapeutic applications.

Energy Metabolism

Cancer cells uptake increased amounts of glucose to satisfy their metabolic demands (52), and this is the basis of fluorodeoxyglucose (FDG)-PET imaging. Normal tissues generate energy using mitochondrial oxidative phosphorylation and only switch to breaking down glucose to derive energy in the absence of oxygen, which leads to the accumulation of lactate. In contrast, glycolysis of glucose to lactate occurs in cancers even in the presence of oxygen, a phenomenon called 'aerobic glycolysis.' This is referred to as the Warburg effect, in honor of its discoverer (53). Because cancers often outgrow their blood supply and become hypoxic, the ability to survive using aerobic glycolysis instead of oxidative phosphorylation may be selected for during malignant transformation. Lactate production by cancers may also promote invasion and metastasis by acidifying the microenvironment. Aerobic glycolysis also may serve the increased metabolic requirement for carbon atoms to produce the macromolecules needed to build new cancer cells. If glucose is completely broken down to carbon dioxide via the citric acid cycle, these carbon building blocks are lost.

The hypoxia-inducible transcription factor-1 α (HIF-1 α) plays an important role in the cellular response to decreased oxygen in the local environment. When oxygen is absent, HIF-1 α accumulates and promotes transcription of pro-angiogenesis genes as well as those involved in glucose transport and glycolysis. HIF-1 α accumulation may be a consequence of loss of the

VHL tumor suppressor gene, providing a link between the loss of a tumor suppressor and the altered metabolic phenotype of malignant cells. Another link between glucose metabolism and cancer is the finding that isocitrate dehydrogenase (IDH), an enzyme involved in glycolysis, is frequently mutated in glioblastomas. The common amino acid changing IDH mutations result in increased production of 2-hydroxyglutarate, which accumulates to high levels and plays a role in the development of these cancers. Activation of the PIK and RAS pathways also regulate glucose uptake and metabolism.

Differences in metabolism between normal and malignant cells represent an appealing therapeutic target. In this regard, there is a suggestion that the diabetic drug metformin may have efficacy in the treatment and prevention of cancer. This appears to be independent of blood glucose level, and the exact mechanism is unclear.

DNA REPAIR

It has been estimated that thousands of mutations occur in humans on a daily basis (54). Cells in many organs such as the skin, gastrointestinal tract, and respiratory tract that are exposed most directly to the environment constantly undergo renewal with shedding of differentiated cells that may contain mutations. Mammalian cells also have highly evolved and complex DNA repair systems to maintain the integrity of the genome. A series of cell cycle checkpoints exist that allow the opportunity to pause for successful DNA repair, or alternatively for cell death if repair cannot be accomplished. DNA damage checkpoints occur at the boundaries between G1/S and G2/M and during S phase and mitotic spindle assembly. These checkpoints serve to protect against genetic damage that can lead to malignant transformation being fixed in the genome.

There are several repair mechanisms that operate on specific types of DNA damage during these checkpoints (55,56), including mismatch repair (MMR), nucleotide excision repair (NER), base-excision repair (BER), homologous recombination (HR)

repair and nonhomologous end joining (NHEJ). Loss of DNA repair activity increases the likelihood of mutations being fixed in the genome and this is a hallmark of many cancers.

DNA Mismatch Repair (MMR)

MMR excises nucleotides that are incorrectly paired with the correct nucleotide on the opposite DNA strand (55). It involves recognition of a base pair mismatch, recruitment of repair enzymes, excision of the incorrect sequence and re-synthesis by DNA polymerase using the parental strand as a template (Fig. 2.9). The recognition of small loops generated by insertion or deletion of nucleotides, as well as single base mismatches is primarily accomplished by a complex called MUTS, which is a heterodimer of MSH2 and MSH6. MLH1 and PMS2 are recruited to the site to initiate the subsequent steps of repair, including excision, DNA synthesis, and ligation.

Loss of mismatch repair leads to a “mutator phenotype” in which there is accumulation of genetic mutations throughout the genome, particularly in repetitive DNA sequences called microsatellites. Examples of microsatellite sequences include mono (AAAA), di (CACACACA), and tri (CAGCAGCAGCAG) nucleotide repeats. Replication errors in these repetitive sequences are common and their inefficient repair leads to the propensity to accumulate mutations, and this is referred to as microsatellite instability (MSI). Some microsatellite sequences are in noncoding areas of the genome while others are within genes. It is thought that accumulation of mutations in microsatellite sequences of tumor suppressor genes may inactivate them and accelerate the process of malignant transformation.

About 3% of endometrial cancers arise due to inherited mutations in MMR genes in the context of Lynch syndrome (57,58). Most cases are due to alterations in MSH2 and MLH1, but MSH6 and PMS1, PMS2, and MSH3 mutations also occur. Lynch syndrome is covered in depth in Chapter 3. More frequently, the MLH1 MMR gene is inactivated due to promoter methylation in sporadic endometrial cancers of the endometrium leading to microsatellite instability.

FIGURE 2.9. Mismatch repair pathways. Mismatched bases due to errors in DNA replication or other causes are recognized by the mismatch repair machinery. The initial step involves recognition of simple mismatches by MSH2 and MSH6 (upper panel), or recognition of insertion/deletion loops by MSH2 and MSH3 (lower panel). Subsequent steps involve recruitment of MLH1 and PMS2 to mismatch sites, or MLH1 and MLH3 to insertion/deletion loop sites. This is followed by excision of the respective lesions, DNA synthesis, and ligation to complete the repair.

Nucleotide Excision Repair/Base Excision Repair

The mismatch repair pathway functions primarily in the recognition and repair of replication errors, while the NER and base excision repair (BER) pathways respond to damage caused by DNA damaging agents. NER is an important DNA repair mechanism, as evidenced by the severe human diseases, including Xeroderma pigmentosum, that result from hereditary defects of NER proteins. The NER genes recognize and repair bulky DNA damage caused by environmental carcinogens, ultraviolet light and chemotherapeutic agents such as platinum compounds (Fig. 2.10). Defects in NER proteins predispose to various types of cancer, including skin cancer in Xeroderma pigmentosum (59).

There are two NER pathways: one global pathway involved in scanning the entire genome and another that detects lesions that interfere with elongating RNA polymerases. The proteins required for NER assemble in an ordered stepwise fashion at sites of base damage. This assembly generates a large multiprotein complex namely the “repairosome.” This repair complex can nick the DNA at precise distances on either side of the base damage and these gaps are repaired using the opposite normal DNA strand as a template. There are several proteins involved in NER process including ERCC1, RPA, RAD23A, RAD23B, XPA, XPB, XPC, XPD, XPE, XPF, XPG, CSA, and CSB. *BRCA1* may also play a role in NER. ERCC1 expression may be a marker of cisplatin resistance in cervical cancer, with low expression predicting superior 5-year disease free survival (60).

BER is closely related to NER in that both repair lesions in DNA bases (Fig. 2.10). BER involves repair of small lesions due

FIGURE 2.10. Nucleotide excision repair and base excision repair: Nucleotide excision repair is activated in response to bulky lesions that are generated, for example, by UV irradiation (upper panels). Global genome repair involves proteins identified by complementation groups in patients with xeroderma pigmentosa (XP proteins). Initial recognition of lesions occurs by a complex containing xeroderma pigmentosa C. Transcription coupled repair also involves proteins identified by mutation in Cockayne syndrome (CS proteins), and occurs when RNA polymerase II stalls at the site of lesions. Stalled RNA polymerase II recruits Cockayne syndrome B to the site of damage. Subsequently, DNA is locally unwound around the injured site by a TFIIH complex containing XPB and XPD. This process also involves XPG, CSA, and other proteins for TCR. Once unwound, XPA and replication protein A contribute to stabilization of an open intermediate and recruitment of the ERCC1 and XPF endonucleases that excise the lesion. Subsequent steps involve DNA synthesis and ligation to complete the repair. In BER (lower panels), abasic sites generated by spontaneous hydrolysis, action of DNA glycosylases, or X-ray-induced single-strand breaks are recognized by the APE1 endonuclease, as well as PARP and XRCC1. Subsequent repair is influenced by PARP-mediated ADP ribosylation of histones and other proteins, while XRCC1 serves as a scaffold for recruitment of DNA polymerase β and DNA ligase 3. These latter enzymes catalyze nucleotide reinsertion and ligation into the injured strand as part of the short patch repair pathway (major BER pathway).

to chemicals and X-rays that do not distort the DNA helix. Single bases in DNA can be damaged by several mechanisms, the most common being deamination, oxidation, and alkylation. BER is initiated by DNA glycosylases that recognize a single or small set of altered or inappropriate bases. BER removes damaged bases that could otherwise cause mutations by mispairing or lead to breaks in DNA during replication. The BER system excises the inappropriate base from the genome as a free base, leaving a site of base loss in the DNA. These sites are further repaired and reconstructed by a series of biochemical events.

Deletion of BER genes increases mutation rates and contributes to the development of various cancers. In this regard, somatic mutations in the DNA polymerase Pol β have been found in some human cancers (61). Mutations in POLE have been found by TCGA in a subset of endometrial cancers with the highest mutation rates. Inherited mutations in the DNA glycosylase MUTYH increase susceptibility to colon cancer (62).

Double Strand Break Repair: Homologous Recombination (HR) Repair and Nonhomologous End Joining (NHEJ)

Double stranded DNA damage can be caused by exogenous factors such as ionizing radiation, ultraviolet rays, alkylating agents, chemotherapeutic drugs or by endogenous factors such as reactive oxygen species or errors in cellular DNA metabolism. Following double stranded DNA damage the ATM (Ataxia telangiectasia mutated) and ATR kinases phosphorylate several proteins including CHK1 and CHK2 that initiate cell cycle arrest by way of p53 and this leads to DNA repair that restores genomic integrity or to apoptosis if DNA repair is inadequate (63).

Homologous recombination (HR) is a process that provides high-fidelity, template dependent repair of complex DNA damage such as DNA cross-links, double strand breaks, single strand DNA

gaps and DNA interstrand cross-links (Fig. 2.11) (55,64). The HR pathway involves the following basic steps. Double stranded breaks are recognized by the MRN complex and checkpoint proteins. A 5'-3' exonuclease generates 3' overhangs, which are then coated with replication protein A (RPA). *BRCA1-BRCA2-RAD51* forms a stable complex, (65) and potentiates HR by promoting assembly of RAD51 onto single the stranded ends. A homology search ensues, followed by strand invasion and DNA synthesis. The links between DNA strands (double Holliday junctions) can be resolved to produce exchange between chromosomes (crossovers) or no exchange (noncrossovers). This is a precise repair mechanism that restores the original sequence. If double stranded breaks are not repaired precisely, this can cause deletions, translocations, and fusions in the DNA, producing genomic rearrangements.

Fanconi anemia is an inherited disease characterized hypersensitivity to DNA cross-linking agents and predisposition to cancer. There are over a dozen genes in the Fanconi anemia pathway that cooperate in HR repair of DNA cross-links. Mutations of several of these, including *BRCA1* and *BRCA2*, increase the risk of breast and ovarian cancer. Inherited mutations in other genes involved in HR are associated with predisposition to these cancers, including *RAD51C* (66) and *RAD51D* (67). The relative risk of ovarian cancer for *RAD51D* mutation carriers was estimated to be 6.30. *PALB2* plays a critical role in HR repair through its ability to recruit *BRCA2* and *RAD51* to DNA breaks. This serves as the molecular scaffold in the formation of the *BRCA1-PALB2-BRCA2* complex. *PALB2* confers breast cancer susceptibility and may also play a role in ovarian cancer susceptibility (68). The *BRIP1* gene is involved in the repair of DNA double-strand breaks by HR in a manner that depends on its association with *BRCA1* and rare germline mutations are estimated to increase ovarian cancer risk by about eightfold (69).

DNA double strand breaks may also be repaired through a nonhomologous end joining (NHEJ) repair mechanism, wherein the break ends are directly ligated without the need for a homologous template (Fig. 2.11). Proteins associated with NHEJ include DNA-PKcs, MRE11, RAD50, XRCC4, and DNA ligase IV.

FIGURE 2.11. Double-strand break repair by homologous recombination and nonhomologous end-joining. In homologous recombination (HR), DSBs are recognized by the MRN (Mre11, Rad50, and Nbs1) complex, among other proteins. 5'-3' exonuclease activity results in the generation of single-strand overhangs that are coated with RPA. Mediator proteins such as *BRCA2* and *RAD52* stimulate assembly of a *RAD51* nucleoprotein filament complex that guides subsequent homology search and strand invasion into the homologous strand (e.g., the identical sister chromatid in late S/G2 phase and mitosis). Subsequent DNA synthesis and ligation results in the formation of recombination intermediates that contain double Holliday junctions. These are resolved by resolving enzymes such as the RecQ helicase BLM, in conjunction with topoisomerase 3α. The process of NHEJ involves recognition of DSB ends by the Ku70-Ku80 heterodimer; with subsequent recruitment of DNA-dependent protein kinase. DNA ends are then ligated following recruitment of XRCC4 and DNA ligase 4.

GYNECOLOGIC MALIGNANCIES

Gynecologic cancers vary with respect to grade, histology, stage, response to treatment and survival. It is now appreciated that this clinical heterogeneity is attributable to differences in underlying molecular pathogenesis. Some cancers arise in a setting of inherited mutations in cancer susceptibility genes, but most occur sporadically in the absence of a strong hereditary predisposition. The spectrum of genes that are mutated varies between cancer types. For each type of cancer, there are a few genes that are frequently mutated, while a wider spectrum are altered in a small fraction of cases (70). There also is significant variety with respect to the spectrum of genetic changes within a given type of cancer. Cancers with a similar microscopic appearance may differ considerably at the molecular level. In some instances, molecular features may be predictive of clinical phenotypes such as stage, histologic type, and survival. An understanding of the clinical phenotypes associated with various genetic alterations in gynecologic cancers has the potential to inform prognosis and prediction of response to therapy.

ENDOMETRIAL CANCER

Etiology

Epidemiologic and clinical studies of endometrial cancer have suggested that there are two distinct types of endometrial cancer (71). “Type I” cases are associated with unopposed estrogen stimulation and often develop in a background of endometrial hyperplasia. Obesity is the most common cause of unopposed estrogen and is part of a metabolic syndrome that also includes insulin resistance and overexpression of insulin-like growth factors that may also play a role in carcinogenesis. Type I cancers typically are well differentiated, endometrioid, early stage lesions and have a favorable outcome. In contrast, “Type II” cancers are poorly differentiated and/or nonendometrioid and are more virulent. The prototype Type II tumor is serous but other histologic subtypes such as clear cell and carcinosarcoma are generally included. They often present at an advanced stage and survival is relatively poor. In practice, not all endometrial cancers can be neatly characterized as either type I or type II. However, as the genetic events involved in the development of endometrial cancer have been elucidated, it has been found that alterations often, but not always, are seen primarily in either type I or II cases (72) (Table 2.3).

Similar to other human cancers, endometrial cancers are believed to arise due to a series of genetic alterations. For Type I tumors, it has long been thought that estrogens contribute to the development of endometrial cancer by virtue of their mitogenic effect on the endometrium. A higher rate of proliferation in response to estrogens may lead to an increased frequency of spontaneous mutations. In addition, when genetic damage occurs, regardless of the cause, the presence of estrogens may facilitate clonal expansion. It also has been postulated that estrogens may act as “complete carcinogens” that both promote carcinogenesis by stimulating proliferation and act as initiating agents by virtue of their carcinogenic metabolites. Unopposed menopausal estrogen replacement therapy was reported in the 1970s to increase the risk of endometrial cancer by four- to five-fold. Estrogen has been listed as a known carcinogen by the U.S. Department of Health and Human Services since 1985. In contrast, progestins oppose the action of estrogens both by down

Table 2.3 Characteristics of Type I versus Type 2 Endometrial Adenocarcinomas

	Type 1	Type 2
<i>Clinical features</i>		
Risk factors	Obesity, unopposed estrogen	Older age
Race	White > Black	White = Black
Precursor	Atypical endometrial hyperplasia	none or <i>in situ</i> carcinoma
Histology	Endometrioid	Serous/clear cell
Grade	1, 2	3
Stage	I/II	III/IV
Survival	Favorable	Poor
<i>Molecular features^a</i>		
Ploidy	Diploid	Aneuploid
MSI	35%	Rare
<i>Tumor-suppressor genes</i>		
TP53 mutation	15%	90%
HER-2/ <i>neu</i> amplification	Rare	30%
FBXW7 mutation	10%	30%
PPP2R1A mutation	Rare	25%
ARID1A mutation	40%	10%
PTEN mutation	80%	Rare
MLH1 methylation	35%	None
POLE mutation	10%	Rare
CTCF mutation	25%	None
<i>Oncogenes</i>		
MYC amplification	Rare	25%
FGFR2 mutation	15%	10%

regulating estrogen receptor levels and by decreasing proliferation and increasing apoptosis.

Lynch Syndrome and Microsatellite Instability

About 3% of endometrial cancers occur in women with a strong hereditary predisposition due to germline mutations in DNA mismatch repair genes in the context of Lynch syndrome. First described by Henry Lynch, this syndrome commonly includes malignancies of the colon, endometrium, stomach, and ovary (57). Less frequent malignancies that are part of this syndrome include those arising in the small bowel, upper urinary tract,

brain, and biliary tract. Colorectal cancer is the most common malignancy in Lynch syndrome, which also is sometimes called hereditary non-polyposis colorectal cancer syndrome (HNPCC). The lifetime cancer risks in Lynch syndrome are about 70% for colon cancer, 40% for endometrial cancer, and 10% for ovarian cancer (Lynch syndrome is covered in more detail in Chapter 3).

Lynch syndrome is caused by inherited germline mutations in one of several DNA mismatch repair (MMR) genes—*MLH1*, *MSH2*, and less often *MSH6*, *MSH3*, *PMS1*, and *PMS2*. These defects lead to faulty DNA repair and increased risk of malignancy (57). A hallmark of MMR deficiency is microsatellite instability. Microsatellites are short repetitive regions of DNA that become unstable during replication in the setting of defective MMR. In addition to germline mutations in the MMR genes, epigenetic silencing through promoter methylation, specifically in *MLH1*, is the most common mechanism of microsatellite instability in endometrial cancer (73,74). Methylation of *MLH1* is not a heritable condition associated with Lynch syndrome. Microsatellite instability is found in up to 35% of endometrial carcinomas and is generally restricted to Type I cases (75,76). Methylation of the *MLH1* promoter also has been noted in endometrial hyperplasias (76,77) and normal endometrium adjacent to cancers, suggesting that this is an early event in the development of some of these cancers (78). The clinical significance of microsatellite instability is unclear, but it may be associated with a more or less favorable outcome.

The Cancer Genome Atlas Project (TCGA)

In 2006, TCGA began with studies in glioblastoma and high-grade serous ovarian cancer. The TCGA pilot project confirmed that an atlas of changes could be created for specific cancer types. It also showed that a national network of research and technology teams working on distinct but related projects could pool the results of their efforts, create an economy of scale, and develop an infrastructure for making the data publicly accessible (<http://cancergenome.nih.gov>). The National Institutes of Health has committed major resources to TCGA to collect and characterize more than 20 cancer types. The ovarian cancer project is complete and is discussed below. The endometrial cancer project is nearing completion as this chapter is being written and will be discussed in this section. Each cancer undergoes comprehensive genomic characterization and analysis. The comprehensive data generated by TCGA are available and widely used by the cancer research community through the TCGA Data Portal. The analyses include sequencing of the entire coding regions of each cancer. Additionally, levels of gene expression, including mRNA and microRNA, are measured either through microarray based platforms or using second generation sequencing techniques to sequence the RNA transcriptome. Copy number alterations and methylation events are also assessed through microarray platforms. Some cancers are also hybridized to reverse phase protein arrays when sufficient biomaterial is available.

Inherent in the design of the TCGA program are methodological aspects to be considered when interpreting the data. Only serous and endometrioid subtypes were accrued in the endometrial cancer project. Furthermore, most of the frozen tumor specimens used were collected and banked previously. Thus, larger tumors undoubtedly are overrepresented, because smaller ones are less likely to be banked. There is also an overrepresentation of serous and high grade endometrioid cancers, with underrepresentation of the more common low-grade cancers. This was to assure adequate numbers of the former groups.

TCGA has reclassified endometrioid and serous endometrial cancers in four broad categories using comprehensive genomic approaches (79). One-third of the cancers are characterized by

microsatellite instability (MI) and associated hypermutation. These cancers have a background mutation rate (BMR) that is approximately ten-fold greater than non-MI tumors. These tumors are exclusively Type I endometrioid and have few DNA copy number alterations. The cancers without MI can be further separated into two groups. Serous cases with extensive DNA copy number alterations and genomic instability (similar to that seen in high-grade serous ovarian carcinoma) constitute one group, and endometrioid cases with few or only focal copy number alterations constitute the other. A smaller fourth subgroup contains samples with very high mutation rates (~100-fold or greater than MSS tumors) and is characterized by mutations in *POLE*, a DNA polymerase involved with repairing errors in transcription. Molecular features can be distinctly overlaid onto these four subclassifications and are discussed below.

DNA Copy Number

Early cytogenetic studies described gross chromosomal alterations in endometrial cancers, including changes in the number of copies of specific chromosomes (80). Comparative genomic hybridization studies have also demonstrated areas of chromosomal loss and gain in both endometrial cancers and atypical hyperplasias (81,82). Uterine serous carcinomas are aneuploid and have copy number alterations in nearly every chromosomal arm across the genome. The copy number alterations are similar to those seen in high-grade serous ovarian carcinoma. However, as discussed below, the mutation spectrum of uterine and ovarian serous cancers differs considerably. Endometrioid endometrial cancers with MI have few copy number alterations. The endometrioid cases lacking MI have some focal copy number alterations and can be subdivided into a group with absolutely no copy number alterations and a second group with focal copy number alterations. A subset of samples also has amplification of chromosome 1q. A more global and specific approach, called GISTIC, can be used to identify recurrent focal copy number alterations. TCGA data suggests that this approach identifies approximately 81 focal copy number events including 38 amplifications and 43 deletions (79). Amplifications occur in many oncogenes, including *KRAS*, *PIK3CA*, *PAX8*, *ESR1*, *MYC*, *FGFR1*, *FGFR3*, *ERBB2*, *ERBB3*, and *CCNE1*. Deletions occur in tumor suppressors, including *PTEN*, *RB1*, *NF1*, *WWOX*, and *PARK2*.

Gene Expression

Microarray analysis and other techniques have been developed that allow analysis of mRNA expression of thousands of genes in a tissue sample. Patterns of gene expression have been described using microarrays that distinguish between normal and malignant endometrium and between various histologic types of cancer (83–85). Global gene expression profiles associated with both lymph node metastasis (86) and recurrence (87) also have been identified in endometrial cancer.

TCGA identified three gene expression subtypes in endometrial cancer (79). One subtype contained most of the uterine serous cases and some grade 3 cases thought to be serous-like. One subtype was enriched for hormonally responsive genes and had higher expression of *ESR1* (estrogen receptor) and *PGR* (progesterone receptor). The third subtype was enriched for genes involved in immune regulation. Though these subgroups were associated with clinical outcome, at present it is unclear if they are independent of other known prognostic factors such as stage, grade, and histology. Studies to validate these biomarker panels and molecular-based prediction models are ongoing. These findings will further increase our understanding of the molecular pathogenesis of endometrial cancer and may help predict clinical phenotypes.

Tumor-Suppressor Gene Alterations

TP53

Inactivation of the *TP53* tumor suppressor gene is among the most frequent genetic events in endometrial cancers (46). *TP53* mutation occurs in about 20% to 30% of all endometrial adenocarcinomas and is associated with several known prognostic factors including advanced stage, poor grade, and nonendometrioid histology (88,89). *TP53* missense mutations are more common (~75%) and generally result in overexpression and accumulation of mutant p53 protein, whereas *TP53* truncating mutations (~25%; nonsense and frameshift) result in complete absence of p53 protein. Endometrial cancers that overexpress p53 protein usually harbor missense mutations in exons 5 through 8 of the gene that result in amino acid substitutions in the protein (Fig. 2.12) (88,90–93). These mutations lead to loss of DNA binding activity. Hotspots or areas of very frequent mutation exist at codons 248 and 273. Numerous studies have confirmed the strong association between p53 overexpression and poor prognostic factors and decreased survival (94–98). This is predominantly due to the disproportional frequency of *TP53* mutations in serous and high-grade endometrioid cancers. Nearly 90% of uterine serous carcinomas have *TP53* mutations as do one-third of high-grade endometrioid cases (79). Lower *TP53* mutation frequencies are seen in grade 2 (~10%) and grade 1 (~5%) endometrioid cases.

Although little is known regarding molecular alterations in uterine sarcomas, overexpression of mutant *TP53* occurs in a majority of mixed mesodermal sarcomas of the uterus (74%) and in some leiomyosarcomas (99,100).

PTEN

The *PTEN* tumor suppressor gene encodes a phosphatase that opposes the activity of cellular kinases that stimulate proliferation. *PTEN* is the most commonly mutated gene in endometrial carcinomas (101–103). Deletion of both copies of the gene had previously been thought to be a frequent event, resulting

in complete loss of *PTEN* function. However, the TCGA data suggest that homozygous deletion and mutation infrequently co-occur, as would be expected mechanistically, and homozygous deletion in the absence of mutation is also uncommon (79). More recent data suggest that single copy loss of *PTEN* is uncommon, and most tumors are diploid at this locus. *PTEN* mutations may be deletions, insertions, and nonsense mutations throughout the gene that lead to truncated protein products. In addition, missense mutations in the phosphatase domain can also inactivate *PTEN* function (Fig. 2.13). Loss of *PTEN* in endometrial cancers is associated with increased activity of the PI3 kinase with resultant phosphorylation of its downstream substrate AKT (104). The *PTEN*/AKT pathway is frequently activated in many solid tumors and endometrial cancer appears to be the tumor type with the greatest pathway activation.

Mutations in the *PTEN* gene are associated with endometrioid histology, early stage, and favorable clinical behavior (105). Well-differentiated, noninvasive cases have the highest frequency of mutations. In grade 1 and 2 endometrioid cancers, *PTEN* mutations are found in more than 80% of cases when second generation sequencing is performed. *PTEN* mutations are virtually nonexistent in serous cases with an estimated frequency of 2% to 3%. In addition, *PTEN* mutations have been observed in 20% of endometrial hyperplasias, suggesting that this is an early event in the development of some endometrioid “Type I” endometrial cancers (106). It has been reported that loss of *PTEN* may occur in normal appearing endometrial glands, and it is proposed that this may represent the earliest event in endometrial carcinogenesis (107,108).

Other Mutated Tumor Suppressor Genes

TP53 and *PTEN* were both found to be significantly mutated genes (SMG) in the TCGA project, as evidence by a statistically increased mutation rate compared with an expected base-line mutation rate (BMR) when corrected for the size of the coding region (79). Other noteworthy SMGs in endometrial cancer include *FBXW7*, *ARID1A*, and *PPP2R1A*.

FBXW7 (CDC4) mediates ubiquitin-dependent proteolysis of phosphorylation-dependent ubiquitination and ubiquitin-mediated degradation of *CCNE1* and other putative oncogenes. *FBXW7* has also been reported to regulate *mTOR* signaling and depletion of *FBXW7* results in increased levels of both *mTOR* and phospho-*mTOR*. Data from TCGA and other studies suggests that *FBXW7* is mutated in a substantial fraction (~30%) of uterine serous carcinomas.

ARID1A is a large nuclear protein that participates in chromatin remodeling. It was first reported to be mutated in ovarian endometrioid and clear cell tumors, and subsequently was found to be mutated in approximately 40% of endometrioid endometrial carcinomas. Recent functional studies have demonstrated that *ARID1A* is a tumor suppressor with the ability to inhibit tumor growth.

PPP2R1A is the constant regulatory subunit of the protein phosphatase 2A, a serine threonine/phosphatase, and functions in control of cell growth and division. It is mutated in 20% to 30% of uterine serous carcinomas, but not in ovarian serous carcinomas. *PPP2R1A* mutations are seen in uterine endometrioid tumors at relatively low frequency.

CTCF is a transcription factor that functions as a negative regulator of both *MYC* and *IGF2* suggesting a role as a tumor suppressor. TCGA found *CTCF* to be mutated in nearly 25% of endometrioid cancers, but mutations were not seen in serous cases. These findings suggest varied regulation of *MYC* with direct amplification occurring in serous tumors and loss of inhibition through *CTCF* mutation occurring in endometrioid tumors.

FIGURE 2.12. Mutation of the p53 gene. Endometrial cancer T861 has a missense mutation in codon 248 of the p53 gene that changes the sequence from CGG to TGG and results in the substitution of tryptophan for arginine. On the left is the normal wild-type (WT) sequence.

FIGURE 2.13. Mutational spectrum of the *PTEN* tumor-suppressor gene and *CTNNB1* (β -catenin) oncogene in 68 well differentiated nonhypermutated endometrial cancers from TCGA. Mutations in the *PTEN* tumor suppressor occur throughout the gene, whereas those in the *CTNNB1* oncogene are missense changes in critical amino acids that result in increased activity.

Oncogene Alterations

ERBB2 (*HER-2/neu*)

Alterations in oncogenes have been demonstrated in endometrial cancers, but this occurs less frequently than inactivation of tumor suppressor genes (Table 2.3). Increased expression of the *HER-2/neu* receptor tyrosine kinase initially was noted in 10% of endometrial cancers (97,109,110) and was associated with advanced stage and poor outcome. Recently, it has been suggested that *HER-2/neu* overexpression may be more prevalent in patients with serous endometrial cancers (111–113). In a tissue microarray study of 483 endometrial cancers using immunohistochemical

analysis and fluorescent *in situ*-hybridization (FISH), the highest rate of *HER-2/neu* overexpression and amplification was found in serous carcinomas (43% and 29%), while this was much less frequent in grade 1 endometrioid adenocarcinomas (3% and 1%) (113).

TCGA data indicates that *HER-2/neu* is mutated in ~3% of endometrial tumors (79), but these are generally restricted to the hypermutated samples with microsatellite instability, and thus the significance of these somatic mutations is unclear. However, the gene is amplified in ~25% of uterine serous carcinomas and only ~1% of endometrioid tumors confirming a strong association with histologic subtype. These data also suggest that therapies that target *HER-2/neu* may have a role in the treatment of

uterine serous carcinomas. The levels of *HER-2/neu* overexpression in endometrial cancers are much less striking than in breast cancers. With rare exception, trastuzumab (anti *HER-2/neu* antibody) generally has not been a useful therapy in endometrial cancer. The GOG studied trastuzumab in advanced or recurrent *HER-2/neu*-amplified endometrial cancers. This study confirmed a higher rate of overexpression in serous tumors (28%) than endometrioid tumors (7%). However, there were no major responses to therapy (114).

KRAS

The *RAS* oncogenes undergo point mutations in codons 12, 13, or 61 that result in constitutively activated molecules in many types of cancers. Initially, these codons of the *KRAS*, *HRAS*, and *NRAS* genes were examined in 11 endometrial cancer cell lines (115). Mutations in codon 12 of *KRAS* were seen in four cell lines and three had mutations in codon 61 of *HRAS*. Subsequent studies of primary endometrial adenocarcinomas confirmed that codon 12 of *KRAS* were mutated in about 10% of American cases and 20% of Japanese cases (90,116–118).

TCGA data indicates that *KRAS* is mutated in ~25% of endometrioid cases and rarely in serous cases (79). There is a greater frequency of *KRAS* mutations among the hypermutator endometrioid cases (35%) than the nonhypermutator endometrioid cases (15%). *KRAS* mutations also have been identified in some endometrial hyperplasias (118)–(120), which suggests that this may be a relatively early event in the development of some Type I cancers.

PI3K

The *PTEN* tumor suppressor gene, which negatively regulates PI3K activity, is frequently mutated in Type I endometrial cancers. Conversely, the *PIK3CA* gene is oncogenically activated in some cases. The catalytic subunit of PI3K (*PIK3CA*) is located on chromosome 3q26.3 and activating mutations in this gene have been described in numerous cancer types. The p85- α regulatory subunit of PI3K (*PIK3R1*) has also been reported to be mutated in several cancer types and the p85- β regulatory subunit of PI3K (*PIK3R2*) is mutated, although much less frequently, often in the setting of microsatellite instability.

In an initial study, *PIK3CA* mutations were seen in 36% of endometrial cancers, and 24% of cases had mutations in both *PTEN* and *PIK3CA* (121). In a subsequent study, 39% of endometrial cancers and 7% of atypical endometrial hyperplasias were found to harbor mutations in *PIK3C* (122), implying that *PIK3CA* mutation occur early in tumorigenesis. As in the initial study, a high fraction of cases had co-mutation in both *PTEN* and *PIK3CA*. These and other studies (123) confirm that *PIK3CA* activating mutations occur in both serous and endometrioid endometrial cancers.

TCGA identified *PIK3CA* mutations in ~50% of both serous and endometrioid tumors (79), however *PIK3R1* mutations were generally restricted to endometrioid cases; occurring in ~40%. It has been suggested that one mechanism by which *PIK3R1* mutations are oncogenic is through the disruption of p85- α dimers that stabilize *PTEN* (124). Both inactivation of *PTEN* or activation of *PIK3CA* can lead to activation of *AKT*, which in turn leads to up-regulation of the mTOR. Recent studies have suggested that inhibitors of the *AKT*/mTOR pathway may have a role in the management of endometrial cancer (40,125). Evidence of partial responses and disease stability have been noted with the mTOR inhibitor Temsirolimus (126) and in another study response to agents targeting this pathway was enhanced by selection of patients with *PIK3CA* mutations (42).

CTNNB1 (β -catenin)

Alterations in the WNT pathway involving *E-cadherin*, *APC* and β -catenin (*CTNNB1*) have been noted in endometrial cancers. *E-cadherin* is a transmembrane glycoprotein involved in cell-cell adhesion and decreased expression in cancer cells is associated with increased invasiveness and metastatic potential. *E-cadherin* mutations do not occur in uterine serous cancers (127), but occur somewhat more commonly (~7%) in endometrioid tumors with some predisposition to those cases with microsatellite instability. *E-cadherin* expression may also be down regulated in the absence of mutations (128,129). The cytoplasmic tail of *E-cadherin* exists as a macromolecular complex with the β -catenin and *APC* gene products, which link it to the cytoskeleton. It appears that a critical function of the *APC* tumor suppressor gene is to regulate *GSK3B* phosphorylation of serine and threonine residues (codons 33, 37, 41, 45) in exon 3 of β -catenin, which results in degradation of β -catenin. Mutational inactivation of *APC* allows accumulation of β -catenin, which translocates to the nucleus and acts as a transcription factor to induce expression of cyclin D1 and perhaps other genes involved in cell cycle progression (129).

Germline *APC* mutations are responsible for the adenomatous polyposis coli syndrome and somatic mutations are common in sporadic colon cancers; but *APC* mutations had not been previously described in endometrial cancers (130,131). TCGA has identified *APC* gene mutations but these are mostly restricted to hypermutator cases and may be passengers rather than driver mutations. The *APC* gene may be inactivated in some endometrial cancers due to promoter methylation.

It has been shown that missense mutations in exon 3 of β -catenin lead to the same end result—namely abrogation of the ability of *APC* and *GSK3B* to induce β -catenin degradation—which results in nuclear localization and increased transcriptional activity (132). β -catenin mutations have been observed in several types of cancers including hepatocellular, prostate, colon and endometrial cancers (Fig. 2.13). Nuclear accumulation of β -catenin protein due to mutation of the gene has been reported in about one-third of endometrioid endometrial cancers (131,133). Mutation of β -catenin has not been observed in uterine serous carcinomas. However, TCGA data indicate that the mutational frequency is ~50% in the microsatellite stable/non-hypermutator endometrioid cancers and only 15% to 20% in the MI/hypermutator cases (Fig. 2.13, Table 2.3), suggesting that this is an important driver mutation in cases without MI (79).

FGFR2

Mutations have also been observed in the fibroblast growth factor receptor 2 (*FGFR2*) gene in about 10% of endometrial cancers (134). In TCGA, *FGFR2* mutations were found more commonly in endometrioid cancers, with a slight predilection for MI cases. A recent report indicates that *FGFR2* and *KRAS* mutations occur in a near mutually exclusive pattern. *FGFR2* mutations were found to be associated with a worse outcome among early stage endometrioid tumors (135). Further studies are needed to evaluate the significance of the identified mutations, as well as the potential clinical utility of drugs targeting the receptor (136). A number of agents that target FGF receptors are under development.

Other Oncogenes

Among nuclear transcription factors involved in stimulating proliferation, amplification of members of the *MYC* family have most often been implicated in the development of human cancers. It has been shown that *MYC* is expressed in normal endometrium (137) with higher expression in the proliferative phase. Several studies have suggested that *MYC* may be

amplified in a fraction of endometrial cancers (138,139). TCGA has identified a low frequency of somatic mutations in *MYC*, but 25% of uterine serous cancers have high-level amplification of the gene (79).

OVARIAN CANCER

Etiology

About 10% of ovarian cancers have a strong hereditary component and arise in women who carry germline mutations in cancer susceptibility genes—predominantly *BRCA1* or *BRCA2* (140). The vast majority of ovarian cancer is sporadic and arises due to accumulation of somatic genetic damage. The causes of acquired genetic alterations remain uncertain, but exogenous carcinogens have not been strongly implicated. Cellular proliferation and oxidative stress with free radical formation with associated inflammation at the time of ovulation or in association with endometriosis or infection may also contribute to accumulation of DNA damage. Regardless of the molecular mechanisms involved, reproductive events that decrease lifetime ovulatory cycles (e.g., pregnancy and birth control pills) are protective against ovarian cancer (see chapter 1) (141). The progestagenic milieu of pregnancy and the pill might also protect against ovarian cancer by increasing apoptosis of cells that have acquired genetic damage (142). The action of other reproductive hormones such as estrogens, androgens and gonadotropins also may contribute to the development of ovarian cancers.

Epithelial ovarian cancers are heterogeneous with respect to behavior (borderline vs. invasive), grade and histologic type. It has become increasingly clear that there are striking differences in the molecular pathogenesis of various disease subsets. It has been proposed that ovarian cancers can be classified as Type I or II based on histology, grade, stage, and molecular alterations (Table 2.3) (143). Type I tumors are generally confined to an ovarian mass at diagnosis, and include low-grade serous, mucinous, and most endometrioid and clear cell carcinomas. They are genetically stable and are characterized by mutations in a number of genes including *KRAS*, *BRAF*, *PTEN*, *CTNNB1*, *ARID1A*, and *PPP2R1A*. Type 2, cancers typically present at an advanced stage and are predominantly high-grade serous lesions, but also include high-grade endometrioid, carcinosarcoma, and undifferentiated cancers. This group of tumors has a high level of genetic instability with frequent chromosomal gains and losses and is characterized by *TP53* and *BRCA1/2* mutations.

There is now strong evidence to suggest that all epithelial ovarian cancers have an extraovarian origin (143). High-grade serous cancers of the ovary, fallopian tube, and peritoneum are likely derived from epithelial cells of the tubal fimbria (144). In this regard, most early serous cancers discovered in *BRCA1/2* carriers undergoing prophylactic surgery have been found to originate in the fallopian tube fimbria, and are associated with preinvasive serous tubal *in situ* carcinomas (STICs) that overexpress mutant *TP53*. In contrast, most endometrioid and clear cell cancers are thought to develop in deposits of endometriosis on the ovary or other pelvic structures. The origin of mucinous ovarian cancers is less clear and some may represent metastases from the gastrointestinal tract. It has been postulated that some mucinous and Brenner tumors arise from embryonic rests near the ovary.

As our understanding of the molecular pathogenesis of ovarian cancer continues to mature, it is likely that the various ovarian cancer subsets will increasingly be thought of as distinct entities with respect to diagnosis, treatment, and prevention. In view of this, each of the subtypes is discussed separately below.

High-Grade Serous Ovarian Cancer

High-grade serous ovarian cancer was the second cancer analyzed by TCGA project (145). This comprehensive genomic analysis confirmed prior findings, most notably these cancers are characterized by a high degree of genetic instability with many copy number alterations and inactivation of *TP53* and *BRCA1/2* and other genes in the homologous DNA repair pathway. Some previously unreported alterations also were discovered. This section will put the new TCGA data in perspective with prior studies. Additional information regarding the findings of the genomic analysis performed by the TCGA can be found in the 2011 publication and in the accompanying supplemental data (145).

DNA Copy Number Alterations

Most high-grade serous ovarian cancers are characterized by extensive genetic instability. Initially gains and losses of various segments of the genome were demonstrated using karyotyping and later at a finer level using comparative genomic hybridization (CGH) (146). Likewise, loss of heterozygosity (LOH), indicative of deletion of specific genetic loci, also was demonstrated to occur at a high frequency on many chromosomal arms (147). Most recently, it has been possible using next generation sequencing to characterize chromosomal rearrangements at the level of the actual base sequence that facilitates analysis of their functional significance (148).

TCGA examined DNA copy number alterations in 489 cases using a variety of high-resolution platforms (145). There were eight chromosomal regions with recurrent gains and 22 with losses, all of which had been described previously. There were 63 recurrent focal amplifications that encoded eight or fewer genes. The most common focal amplifications included *CCNE1* (cyclin E), *MYC* and *MECOM*, each of which was amplified in more than 20% of cancers.

It was already known prior to the TCGA study that increased activity of transcription factors such as *MYC* and various cyclins may stimulate malignant transformation. Amplification of *MYC* had been reported to occur in some ovarian cancers (149) as had amplification and overexpression of cyclin E (150,151). In studies of advanced stage ovarian cancers, high cyclin E expression was associated with poor outcome (150,152). Alterations of the PI3K pathway are frequent in ovarian cancer and it also previously had been reported that the *AKT2* (153) and *PIK3CA* gene are amplified in some cases (154).

TCGA found 50 focal deletions, and the known tumor suppressor genes *PTEN*, *RB*, and *NF1* were deleted, albeit only in a small fraction of cases (145). The latter two genes also were targeted by mutations, consistent with the two hit paradigm of tumor-suppressor gene inactivation. Although mutations in the *RB* tumor suppressor gene are not a common feature of ovarian cancers, evidence suggests that inactivation of *RB* greatly enhances tumor formation in the presence of *TP53* mutations (155). A large number of other candidate genes are in regions that are recurrently amplified or deleted in high-grade serous ovarian cancers. Considerable effort will be required to elucidate which of these represent driver events in some cancers, as opposed to alterations of no consequence for tumorigenesis or progression.

About 30% of breast cancers express increased levels of the *HER-2/neu* oncogene (156), usually due to gene amplification. Overexpression of *HER-2/neu* in breast cancer has been associated with poor survival. Expression of *HER-2/neu* is increased in a fraction of ovarian cancers (Fig. 2.14) and overexpression has been associated with poor survival in some studies (156,157). However, ovarian cancers with *HER-2/neu* overexpression rarely have high-level gene amplification. Anti-*HER-2/neu* antibody therapy (trastuzumab) has demonstrated great

FIGURE 2.14. Overexpression of *HER-2/neu* in ovarian cancer. **A:** Serous ovarian cancer. **B:** Immunostaining for *HER-2/neu* demonstrates intense cell membrane staining indicative of overexpression.

efficacy in breast cancer and often is administered with chemotherapy in the context of both adjuvant therapy and treatment of metastatic disease (158). The use of this drug is restricted to patients whose cancers are shown to overexpress *HER-2/neu* based on immunohistochemical analysis of protein levels and/or FISH analysis of gene amplification in paraffin tumor tissue blocks. A study performed by the Gynecologic Oncology Group found that only 11% of ovarian cancers exhibited significant *HER-2/neu* overexpression (159). The response rate to single-agent trastuzumab therapy was disappointingly low (7%), but there may be some benefit using it in regimens that also include cytotoxics or other biological agents.

The cyclin dependent kinases (cdk) inhibitors act as tumor suppressors by virtue of their inhibition of cell cycle progression from G1 to S phase. Expression of several cdk inhibitors appears to be decreased in some ovarian cancers. *CDKN2A* (p16) undergoes homozygous deletions in about 15% of ovarian cancers (160). There is evidence to suggest that *CDKN2A* (161) and *CDKN2B* (p15) (162) may be inactivated via transcriptional silencing due to promoter methylation rather than mutation and/or deletion. Likewise, decreased expression of the p21/*WAF1* cdk inhibitor has been noted in a significant fraction of ovarian cancers despite the absence of inactivating mutations (163). Loss of p27 (*CDKN1B*) also may occur and correlates with poor survival in some studies (164). It has been suggested that aberrant expression of p27 in the cytoplasm may be most associated with poor outcome (165).

Mutations

TCGA performed sequencing of the coding regions and splice sites of about 18,500 genes in DNA isolated from 316 high-grade serous ovarian cancers (145). The extent of this sequencing effort in ovarian cancer was unprecedented and would not have been possible without the recent development of massively parallel sequencing technologies. Although several genes were identified that are mutated at low frequencies, *TP53*, *BRCA1* and *BRCA2* were confirmed to be the most frequently genes in high-grade ovarian cancers.

TP53

The TCGA study validated the prior finding that mutation of the *TP53* tumor suppressor gene is the most frequent genetic event in high-grade serous ovarian cancers (Table 2.4) (166–169). It is

an early event that is found in serous tubal carcinoma *in situ* (Fig. 2.15) (144). About two-thirds of high-grade serous ovarian cancers have *TP53* missense mutations in the DNA binding regions of exons 5 through 8 of the gene that result in p53 protein overexpression due to increased stability of the protein. Codons 175, 248 and 273 are mutational hot spots. These missense mutants act as dominant negative transforming genes due to their nonfunctional transcriptional activity. Loss of the other copy of the *TP53* gene is not required. Most *TP53* missense mutations are transitions rather than transversions or micro-deletions (170), which suggests that they occur spontaneously, rather than due to exogenous carcinogens.

Overexpression of mutant p53 protein may be associated with somewhat worse survival in advanced stage ovarian cancers (167,169,171). However, reports in the literature are inconsistent and are often confounded by the inclusion of ovarian cancers of various stages, grades, and histological types. Most high-grade serous ovarian cancers that do not overexpress p53 protein have *TP53* mutations that result in truncated protein products (166,171). These are usually accompanied by loss of the other copy of the gene, consistent with the classic two hit

Table 2.4 Characteristics of Common Invasive Epithelial Ovarian Carcinomas

	Mucinous	Endometrioid/ Clear Cell	High-grade Serous	Low-Grade Serous
Origin	Unclear	Endometriosis	Fallopian Tube Epithelial Cells	Fallopian Tube Epithelial Cells
Typical stage	Early	Early	Advanced	Early
Survival	Favorable	Favorable	Poor	Favorable
Commonly altered genes	<i>KRAS</i> <i>HER-2/neu</i>	<i>PTEN</i> <i>CTNNB1</i> (β -catenin) <i>ARID1A</i> <i>PPP2R1A</i> <i>PIK3CA</i>	<i>TP53</i> <i>BRCA1</i> <i>BRCA2</i>	<i>KRAS</i> <i>BRAF</i>

FIGURE 2.15. Overexpression of mutant *TP53* in serous tubal carcinoma in situ (**A, B**) and in high-grade serous ovarian cancer (**C, D**).

model of tumor-suppressor gene inactivation. TCGA found *TP53* mutations in 303 of 316 samples, suggesting that this is essentially a requisite event in the development of high-grade serous cancers.

BRCA1 and BRCA2

BRCA1 and *BRCA2* germline mutations were found in 9% and 8% of high-grade serous cases respectively in the TCGA study, and somatic mutations occurred in an additional 3% (145). Silencing of *BRCA1* due to promoter methylation was observed in 11% of cases as has been previously described (172,173). Defective HR repair of double stranded DNA damage due to loss of *BRCA1/2* was predicted in 31% of high-grade serous ovarian cancers. Other genes in the HR pathway are inactivated in some cancers and the HR pathway may be compromised in about half of cases (Fig. 2.16). Patients with *BRCA1* or *BRCA2* mutations have increased sensitivity to platinum chemotherapy and favorable survival relative to sporadic cases (174,175). Conversely, the emergence of platinum resistance in these cancers may occur due to “back mutations” in which the normal *BRCA1* or *BRCA2* sequence is restored (176).

Cancers with defects in the double stranded DNA HR repair pathway can be targeted effectively by inducing a second hit in the form of inhibition of the single stranded DNA repair pathway. This concept of synthetic lethality—the combination

of two genetic alterations, which on their own are nonlethal, but together result in a lethal phenotype—led to interest in inhibitors of enzymes such as poly-ADP ribose polymerase (PARP) that are involved in single stranded BER (177). Inhibition of PARP leads to the persistence of DNA lesions normally repaired by HR and makes HR-deficient cells particularly sensitive to chemotherapy-induced DNA injury (178). PARP inhibitors have been shown to be selective for cells with defects in the repair of double-strand DNA breaks by HR, particularly in the context of *BRCA1* or *BRCA2* mutation. While normal cells can repair the damage and survive, the *BRCA*-deficient cells cannot activate the HR system and therefore die (179). PARP inhibitors have demonstrated promising results in ongoing trials in ovarian cancer (180).

While only a minority of high-grade serous ovarian cancers have germline *BRCA1* or *BRCA2* mutations, sporadic ovarian cancers can harbor acquired genetic and epigenetic defects in *BRCA1/2* and in other HR genes and proteins, such as *RAD51* that may contribute to a “BRCaness profile” (181). Given the shared role that *BRCA1* and *BRCA2* have with other DNA repair genes, defects in these other DNA repair proteins could influence response to treatment, recurrence rates, and overall survival and increase sensitivity to platinum drugs and PARP inhibitors. In this regard, it was shown using the TCGA data that a DNA repair pathway score was predictive of outcome in ovarian cancer (182).

Extent of HR Defects in TCGA Ovarian Samples

FIGURE 2.16. Genomic fingerprint of HR pathway alterations. Each column represents an individual case; each row represents a gene. Only cases with HR defects (N = 154) are shown. HR: homologous recombination.

Other mutations

Six other genes were found to be significantly mutated by TCGA, including *RB*, *NF1*, *FAT3*, *CSMD3*, *GABRA6*, and *CDK12*, but none was mutated in more than 6% of cancers (145). *RB* and *NF1* are known tumor suppressor genes, while *CDK12* has also been implicated in regulation of RNA splicing. *FAT3* and *GABRA6* are not expressed in serous ovarian cancers or in the fallopian tube and the significance of these mutations is unclear. A number of other known oncogenic mutations were found in *KRAS*, *NRAS*, *PIK3CA* and *BRAF*, but at low frequencies less than 1%. These mutations have been shown to have transforming activity and probably represent important drivers of some cancers.

Gene Expression

Microarray chips that contain sequences complementary to thousands of genes have been created that allow global assessment of the level of expression of each gene. Many genes have been identified that appear to be up or downregulated in the process of malignant transformation (183). In addition, microarrays have demonstrated patterns of gene expression that distinguish between histologic types (184), borderline versus invasive cases (185) and between early and advanced stage disease (186). Molecular signatures also have been identified that are predictive of response to therapy (187) and survival (187,188).

In the TCGA ovarian cancer project, a 193 gene expression signature predictive of survival was developed and validated in several other existing data sets (145). The TCGA also identified four gene expression subtypes of high-grade serous ovarian cancer (145). These were named mesenchymal, immunoreactive, differentiated, and proliferative based on the genes that characterized each subtype. Although the subtypes were independently validated in several other microarray data sets, they are not strongly predictive of response or outcome. Alterations in gene expression may be attributable to methylation of their promoters. The TCGA examined methylation using arrays that include promoters of thousands of genes. They found 168 epigenetically altered genes compared to normal fallopian tube epithelium.

Further validation of genomic signatures is needed, but genomic approaches hold the potential to guide selection of therapy in the future. Patients identified as having a “poor prognosis” molecular profile might be the best candidates for

investigational trials of new therapies. Microarray analyses have also demonstrated that dysregulation of oncogenic pathways varies considerably between ovarian cancers (189). This may provide the opportunity to incorporate biological therapies that target oncogenic pathways based on an understanding of the underlying molecular alterations in a patient’s cancer.

With the evolving characterization of the genome, networks of molecular signals that regulate cellular proliferation and death have been identified—from receptor ligand interactions at the cell membrane that transmit signals to the cytoplasm and then to the nucleus. The extensive genomic characterization of high-grade serous ovarian cancer by TCGA allowed for assessment of various signaling pathways. It was found that components of the *RB* and *PI3K/RAS* pathways were frequently altered while the homologous DNA repair pathway was frequently inactivated.

Borderline and Invasive Low-Grade Serous Ovarian Cancers

Similar to high-grade serous cancers, it is thought that borderline and low-grade serous cancers also likely arise from cells that originated in the fallopian tube epithelium. However, the underlying genetic alterations in borderline and low-grade tumors are different from those of high-grade cancers, suggesting that they are distinct entities rather than a single disease with varying degrees of differentiation.

Activating mutations in codons 12 and 13 of the *KRAS* oncogene are common in borderline serous ovarian tumors, occurring in about 25% to 50% of cases (190). In addition, activating mutations in codon 599 of *BRAF*, which is a downstream effector of *KRAS*, occur in about 20% of serous borderline tumors (191). Mutations in these two genes are mutually exclusive and result in constitutive activation of the MAP kinase pathway. Mutations in *KRAS* and *BRAF* have also been noted in cystadenoma epithelium adjacent to serous borderline tumors, suggesting that this is an early event in their development (38). Likewise, mutations in *BRAF* and *KRAS* occur in some low-grade serous ovarian cancers (143), but these mutations are rarely seen in high-grade serous ovarian cancers. Since metastatic low-grade serous and borderline cancers are generally resistant to platinum/taxane therapy, the MAP kinase pathway downstream from *KRAS/BRAF* represents an appealing target in ongoing clinical trials (192).

Overexpression of p53 protein is rare in stage I serous borderline tumors and well-differentiated serous cancers, but occurs in a minority of advanced stage borderline cases (193,194). In a study of advanced serous borderline tumors, p53 overexpression was associated with a sixfold higher risk of death (193). In some cases, invasive low-grade serous cancers may arise following an earlier diagnosis of borderline tumor. It has been shown that *TP53* mutational status was not concordant between the original borderline tumor and the subsequent invasive cancer (195). This suggests that the invasive cancer arises either independently or as a clonal outgrowth within the original tumor.

Endometrioid and Clear Cell Ovarian Cancers

About 20% of epithelial ovarian cancers have endometrioid or clear cell histology and these are thought to arise in pelvic endometriosis, usually on the ovary. Clear cell cancers and low-grade endometrioid cancers have a lower level of genetic instability than high-grade serous cases. The most common alterations in clear cell cancers are mutations of the *ARID1A* tumor suppressor gene, which is involved in chromatin remodeling, and this occurs in about 50% of cases (196,197). *ARID1A* mutations have been observed in the tumor and contiguous atypical endometriosis, but not in distant endometriotic lesions. This suggests that *ARID1A* mutations are an early event in the development of these cancers. The PI3K pathway is also frequently altered, and activating mutations of *PIK3CA* occur in about 50% of cases, and deletion of the *PTEN* tumor suppressor in about 20% (198). *PPP2R1A* encodes the α -isoform of the scaffolding subunit of the serine/threonine protein phosphatase 2A (PP2A) holoenzyme. This putative tumor suppressor complex is involved in growth and survival pathways. Missense mutations in this gene were noted in about 5% of clear cell carcinomas (196).

Mutations of these same genes also occur in endometrioid cancers: *ARID1A* (30%), *PIK3CA* (20%) and *PTEN* (20%), *PPP2R1A* (10%) (199,200). In addition, about 30% of endometrioid cancers have mutations the *CTNNB1* gene that encodes β -catenin, a nuclear transcription factor involved in the WNT pathway. These mutations occur in exon 3 at or adjacent to the serine/threonine phosphorylation sites and stabilize the protein product leading to nuclear overexpression and increased transcriptional activity. In some endometrioid ovarian cancers with abnormal nuclear accumulation of β -catenin that lack mutations in this gene, the *APC*, *AXIN1*, or *AXIN2* genes that regulate β -catenin activity are mutated (201). This suggests that in addition to the mutations that are also present in clear cell cancers, endometrioid cancers frequently have alterations in the WNT signaling pathway (Table 2.4). Mouse models in which the WNT and the PIK3/PTEN pathways are inactivated leads to the development of endometriosis and endometrioid cancers (202,203). Targeting of the latter pathway has some efficacy in recurrent ovarian cancers (204).

High-grade endometrioid ovarian cancers typically have molecular features similar to high-grade serous ovarian cancers, including genetic instability and *TP53* mutations. This suggests that these tumors may sometimes be misclassified by pathologists based on light microscopy.

Synchronous Endometrioid Ovarian and Endometrial Cancers

As noted above, about 20% of endometrioid ovarian cancers have *PTEN* mutations (200). Synchronous endometrioid cancers are sometimes encountered in the endometrium and ovary that are indistinguishable microscopically. In some of these cases, identical *PTEN* mutations have been identified suggesting

that the ovarian tumor represents a metastasis from the endometrium (205). In other cases, the *PTEN* mutation seen in the endometrial cancer was not found in the ovarian tumor suggesting that these represent two distinct primary cancers. Mutational analysis of *PTEN*, *CTNNB1* and other genes frequently mutated in endometrioid cancers is helpful when a mutation is present in both cancers or in one cancer and absent in the other, but this approach often may often be uninformative. It has been reported that mitochondrial DNA mutations are fairly common in endometrial cancers (206), and mitochondrial DNA sequencing has been proposed as an alternative method of determining whether synchronous endometrioid cancers of the ovary and endometrium represent separate primary cancers.

Mucinous Ovarian Cancer

Similar to mucinous colorectal cancers, mucinous ovarian cancers frequently have *KRAS* mutations (143). These mutations occur in 50% to 75% of mucinous ovarian cancers and are missense changes in the hotspot codons. *BRAF* mutations have not been found in mucinous ovarian cancers (207). Identical *KRAS* mutations have been found in mucinous carcinomas and adjacent mucinous cystadenomas and borderline tumors, suggesting that the latter lesions represent premalignant precursors (143). Amplification of *HER-2/neu* has also been described in a subset of mucinous ovarian cancers (143). *TP53* and other genes that are mutated in other histological types of ovarian cancer have not been found to be altered in mucinous cancers. These findings are supportive of the theory that many mucinous ovarian cancers may be metastatic from the gastrointestinal tract.

Stromal Ovarian Tumors

The genetic alterations driving stromal tumors of the ovary were unknown until recently when it became possible to screen the entire genome using next generation sequencing. Essentially all adult granulosa tumors were found to have a missense mutation in codon 134 of *FOXL2*, a gene encoding a transcription factor known to be critical for granulosa cell development (208). This mutation was also found in about 20% of thecomas and in 10% of juvenile granulosa cell tumors, but not in other types of sex cord stromal tumors. In addition, *DICER1* mutations in the RNase IIIb domain were found in about 30% of nonepithelial ovarian tumors, predominantly in Sertoli-Leydig cell tumors (60%) (209). These mutations were restricted to codons encoding metal-binding sites within the RNase IIIb catalytic centers, which are critical for microRNA interaction and cleavage.

CERVICAL CANCER

Etiology

Although the incidence of cervical cancer has fallen by over 80% in developed countries due to widespread implementation of cervical screening, in developing areas of the world it is still the most common cancer in women. Almost all cervical cancers are caused by sexually transmitted human papilloma virus (HPV) infection, as are many vaginal and vulvar cancers. The epidemiology and biology of HPV infection and its role in screening and prevention are discussed in Chapters 1 (Epidemiology) and 7 (Preinvasive lower genital tract disease).

Unlike most other types of human cancers that occur due to mutations in oncogenes and/or tumor suppressor genes that disrupt their normal genetic sequence, cervical cancers arise as a consequence of viral inactivation of the *TP53* and *RB* tumor

FIGURE 2.17. Role of *TP53* and *RB* genes in cervical carcinogenesis. The HPV 16/18 E6 and E7 proteins inactivate the *TP53* and *RB* genes respectively.

suppressors by the HPV E6 and E7 oncoproteins respectively (Fig. 2.17) (210). Variations in oncogenic potential between HPV subtypes may be related in part to differences in the efficiency with which E6 and E7 bind to and inactivate these tumor suppressors (211,212). In some studies, the levels of E6 and E7 in invasive cervical cancers have been found to predict outcome, whereas HPV viral load does not (213). There is also evidence that HPV E6/E7 may interact directly with other genes such as telomerase that enhance growth and inhibit apoptosis. In addition, the cyclin dependent kinase inhibitor p16 is strikingly upregulated in most cervical dysplasias and cancers (214). P16 detection may represent a useful adjunct to improve the positive predictive value of high-risk HPV testing for detection of cervical dysplasia.

HPV negative cervical cancers are uncommon, but have been reported to exhibit overexpression of mutant p53 protein (215). This suggests that inactivation of *T53* is a requisite event in cervical carcinogenesis. The biology of HPV related transformation, including the role of E6/E7, is discussed in greater detail in Chapter 7. This chapter will focus on the secondary genetic alterations that have been observed in invasive cervical cancers.

Secondary Genomic Changes

HPV associated cervical carcinogenesis with inactivation of the *TP53* tumor suppressor gene leads to genomic instability that results in secondary genetic alterations that play a role in the development and phenotype of these cancers. Over time this ongoing instability leads to significant intratumoral heterogeneity as genetic damage continues to accumulate. Most cervical cancers are aneuploid and comparative genomic hybridization studies have shown that areas of DNA copy number gain or loss are common. A strikingly consistent finding of various studies is the high frequency of gains on chromosome 3q in both squamous cancers (216,217) and adenocarcinomas (218). Other chromosomes that exhibit frequent gains include 1q and 11q. The most common areas of chromosomal loss include chromosomes 3p and 2q and 13q (219). The frequency of gains and losses at various genomic locations may be random to a certain extent, but there are areas of the genome that are more susceptible to breakage leading to translocations or loss/gain. Abnormalities seen in invasive cancers using comparative genomic hybridization also have been identified in high-grade dysplasias, suggesting that these are early and perhaps requisite events in cervical carcinogenesis (217,220,221).

Alterations in gene dosage due to chromosomal gains or losses have the potential to lead to changes in expression of genes involved in regulation of processes central to malignant transformation such as growth, differentiation, and apoptosis. Cervical carcinogenesis is also accompanied by changes in DNA

methylation that affect gene expression. Regardless of the cause, some changes in gene dosage likely represent collateral damage and have no effect on development and evolution of the malignant phenotype. However, it is likely that over time there is selection for clones that exhibit enhanced growth and invasive potential. It is possible that genetic instability may also enhance the emergence of resistance to radiation and chemotherapy.

A recent study examined gene dosage in locally advanced cervical cancers using microarrays. Alterations were frequent and there were 14 regions with recurrent gains and 14 with recurrent loss. The most common alterations were gain on 1q, 3q, 5p, 20q, and Xq and loss on 2q, 3p, 4p, 11q, and 13q, each involving 44% to 76% of the patients. Four genes on 3p (*RYBP*, *GBE1*) and 13q (*FAM48A*, *MED4*) correlated with outcome at both the gene dosage and expression level and were validated in the independent cohort. Despite circumstantial evidence provided by studies such as this, with the exception of the fragile histidine triad (*FHIT*) gene on chromosome 3p14, it has been difficult to prove that genomic gains and losses result in alterations in specific oncogenes or tumor suppressor genes that are directly involved in tumor development. The *FHIT* gene is frequently deleted in many different cancers, including cervical cancer (222-224). Decreased expression of this putative tumor suppressor gene is an early event in some cervical cancers (224,225). In one study, *FHIT* protein expression was markedly reduced or absent in 71% of invasive cancers, 52% of HSILs associated with invasive cancer, and 21% of HSILs without associated invasive cancer (224). In addition, reduced expression is associated with poor prognosis in advanced cervical cancers (226).

The role of several oncogenes has been examined in cervical carcinomas including most prominently the *RAS* and *MYC* genes. Mutant *RAS* genes are capable of cooperating with HPV in transforming cells *in vitro*. There is some evidence that mutations in either *KRAS* or *HRAS* may play a role in a subset of cervical cancers (215,227-230). *MYC* amplification and overexpression may be an early event in the development of some cervix cancers (231). Overexpression of *MYC* has been demonstrated in one-third of early invasive carcinomas and some CIN 3 lesions. In some studies, amplification correlated with poor prognosis in early stage cases (232).

Gene silencing due to promoter hypermethylation also may play a role in cervical carcinogenesis (233,234). In this regard, expression of the *RASSF1A* gene on chromosome 3p21 is frequently lost in cervical cancers, particularly adenocarcinomas (235,236). The function of this gene is not completely understood, but is thought to be involved in ras mediated signal transduction pathways. Hypermethylation of genes associated with programmed cell death (apoptosis) and tumor suppressor genes have also been described in cervical cancers.

GESTATIONAL TROPHOBLASTIC DISEASE

The genetic alterations that underlie gestational trophoblastic disease have been elucidated to a great extent. The most prominent feature of these tumors is an imbalance of parental chromosomes. In partial moles, this involves an extra haploid copy of one set of paternal chromosomes (XXY, XXX, or YYY). Complete moles generally are characterized by two pairs of one paternal haploid set of chromosomes (XX) and an absence of maternal chromosomes, while a minority are (XY) due to dispermy. Although the risk of repeat molar pregnancy is only about 1%, women who have had two molar pregnancies have about a 25% risk of developing another mole. Although this suggests a hereditary defect that affects gametogenesis, this remains speculative. Thus far, there is no convincing evidence that damage to specific tumor-suppressor genes or oncogenes contributes

to the development of gestational trophoblastic disease. However, the presence of two identical copies of each chromosome in most complete moles could facilitate transformation due to increased or decreased expression of imprinted genes involved in growth regulatory pathways. In addition, inactivation of a tumor-suppressor gene on a paternal chromosome that might not normally be manifest because of the presence of a wild-type allele on the maternal chromosome could become significant in cells with two copies of the same haploid paternal genome.

Microarray studies have identified several genes that are differentially expressed compared to normal villi, particularly genes associated with cellular apoptosis, immune suppression,

and cell invasion (237,238). In one study in which genomic techniques were used to compare gene expression between moles that spontaneously regressed and those that subsequently developed metastatic GTN identified 16 differentially expressed transcripts (238). Down-regulation of ferritin light polypeptide (*FTL*) and insulin-like growth factor binding protein 1 (*IGFBP1*) was confirmed in cases that subsequently developed GTN compared with those that regressed. Studies have also suggested that changes in expression of genes involved in apoptosis, such as greater expression of the antiapoptotic gene *Mcl-1*, may be involved in progression of a molar pregnancy requiring chemotherapy (239).

Hereditary Gynecologic Cancers

KAREN H. LU ■ ANDREW BERCHUCK ■ NOAH D. KAUFF

INTRODUCTION

Identifying a woman with gynecologic cancer as having a hereditary cancer syndrome has tremendous implications for both the patient herself and for her family members. Hereditary Breast and Ovarian Cancer syndrome, caused by germline mutations in *BRCA1* or *BRCA2*, as well as Lynch syndrome, caused by germline mutations in *MLH1*, *MSH2*, *MSH6*, or *PMS2*, are the most common hereditary syndromes that include gynecologic cancers as part of their cancer spectrum. Other syndromes that include gynecologic cancers include Cowden's syndrome (*PTEN* germline mutation), Peutz-Jeghers syndrome (*STK11* germline mutation), and Li-Fraumeni syndrome (*TP53* germline mutation) (Table 3.1). All of these syndromes are caused by mutations in tumor-suppressor genes. In order for an individual to develop a cancer associated with one of these syndromes, both the maternally and paternally inherited copy of the relevant gene must be inactivated as described by Knudsen's two hit hypothesis (1). Women with hereditary cancer syndromes have inherited, from either their mother or their father, a nonworking copy of one of the relevant genes and this defect is present in all of their cells.

Table 3.1 Selected Hereditary Cancer Syndromes with Gynecologic Manifestations

Syndrome	Gene	Chromosome	Predominant Cancers
Hereditary breast/ovarian cancer	<i>BRCA1</i>	17q21	Breast, ovary
	<i>BRCA2</i>	13q12	
Lynch syndrome	<i>MSH2</i>	2p16	Colon, endometrium, ovary and urinary tract
	<i>MLH1</i>	3p21	
	<i>MSH6</i>	2p16	
	<i>PMS2</i>	7p22	
Cowden syndrome	<i>PTEN</i>	10q23	Breast, thyroid and endometrial
Li-Fraumeni syndrome	<i>TP53</i>	17p13	Breast, sarcomas, leukemias, and brain
Peutz-Jeghers syndrome	<i>STK11</i>	19p13	Colon, breast, gastric, and ovarian sex cord-stromal tumors with annular tubules (SCTAT)

Therefore, in order for cancer to develop in a susceptible tissue through defects in a specific pathway, only the second working copy of the relevant gene needs to be lost. This is why the cancers occur earlier and more frequently than in the general population. This also explains why not all individuals with an inherited predisposition develop cancer, as it is possible that the second working copy of the relevant tumor suppressor gene is never lost in a susceptible tissue. Further, as these syndromes are all caused by mutations in a single allele of the relevant tumor suppressor gene, they are all autosomal dominant disorders in which each offspring is at 50% risk of inheriting the cancer predisposition.

In recent years, there has been increasing emphasis placed on developing guidelines to assist physicians in recognizing those patients in whom genetic counseling and testing may be helpful. In addition, new prognostic and therapeutic implications that distinguish a cancer patient with a hereditary cancer syndrome have been discovered. Finally, recommendations for prevention of cancer have been refined over the last decade and will be discussed in this chapter.

HEREDITARY BREAST OVARIAN CANCER SYNDROME

Epidemiology

Of all common solid tumors, ovarian, fallopian tube, and primary peritoneal cancers have the highest proportion that is caused by heritable germline mutations, with mutations in *BRCA1* and *BRCA2* accounting for the vast majority. In one series from University of Washington, of 360 patients undergoing primary surgery for epithelial ovarian, fallopian tube, or primary peritoneal cancer, 63 (17.5%) patients had a deleterious mutation in either *BRCA1* or *BRCA2*. Three (0.8%) patients had deleterious mutations in *TP53* and 2 (0.5%) patients had deleterious mutations in *MSH6* (2). Additionally, 17 (4.7%) patients harbored germline loss of function mutations in 1 of 8 other genes known to be important in inherited breast cancer (*CHEK2*, *PALB2*, *BARD1*, *BRIP1*, *RAD50*, *RAD51C*, *NBN*, and *MRE11*), though it is not yet known if risks associated with mutations in these other genes are great enough to be considered causative or if loss of function mutations in these genes act more as modifiers of cancer risk.

When just pelvic serous cancer is examined, 16% to 18% of unselected patients with high-grade pelvic serous cancer have been reported to have a deleterious *BRCA1* or *BRCA2* mutation (3–5). In 2005, Pal and colleagues reported on a population-based series of 121 incident pelvic serous cancers diagnosed in the Tampa, Florida region from 2000 to 2003. In this series, 20 (16.5%) patients had a deleterious *BRCA* mutation identified on sequencing of *BRCA1* and *BRCA2* (3). When the cohort was stratified by family history, mutations

were found in 10 (9.9%) of 101 patients without any family history of breast or ovarian cancer in first- or second-degree relatives. In 2011, Zhang and colleagues reported an updated population-based series of 1342 invasive ovarian cancers ascertained in Ontario, Canada, from 1995 to 1999 and from 2002 to 2004. In this series, 135 (18.0%) of 751 patients with serous ovarian cancer had a deleterious *BRCA1* or *BRCA2* mutation identified (4). Of note, 6.1% of the nonfounder mutations identified in this study were large genomic rearrangements not detected on sequencing and only identified on multiplex ligation-dependent probe amplification (MLPA) testing. In 2012, Alsop and colleagues found 118 (16.6%) *BRCA1* and *BRCA2* mutations in 709 patients with incident pelvic serous cancers ascertained as part of the Australia Ovarian Cancer Study from 2002 to 2006. Additionally, similar to the Pal study, 62 (8.3%) of 749 patients without a significant family had a germline *BRCA* mutation identified, and 44% of all the mutations identified in the study occurred in the absence of a family history (5).

Given this substantial frequency of mutations in women with pelvic serous cancer irrespective of family history, both the American College of Obstetricians and Gynecologists and the National Comprehensive Cancer Network state that it is reasonable to offer testing for *BRCA* mutations to any woman with high-grade serous ovarian cancer if it will impact the care of either the woman or her close family members (6, 7).

Pathology

BRCA1- and *BRCA2*-associated cancers appear to be associated only with specific histological subtypes of ovarian and fallopian tube cancer. In one of the first studies to examine this issue, Boyd and colleagues genotyped 189 consecutive Jewish patients with invasive epithelial ovarian cancer, seen at Memorial Sloan-Kettering Cancer Center for the 3 common Ashkenazi founder mutations. Of the 88 patients with a founder mutation in *BRCA1* or *BRCA2*, 60 (68%) had serous ovarian cancer and 12 (14%) had adenocarcinoma, not otherwise specified. Twelve (14%) and 2 (2%) patients had endometrioid and clear cell ovarian cancer, respectively. No patient with mucinous ovarian cancer had a *BRCA* mutation (8). More recently, in the 2011 Zhang report, 82% of *BRCA*-associated cancers were serous, 16% were endometrioid, 1.2% were clear cell, and 0% were mucinous (4).

It should be noted that, in most of the studies to date, the proportion of endometrioid and clear cell carcinomas associated with *BRCA* mutations may be overrepresented. *BRCA*-associated serous ovarian cancers have been reported to appear “pseudo-endometrioid,” resulting in misclassification unless serous specific immunohistochemical markers are used (9). In the 2012 Alsop report, *BRCA1* or *BRCA2* mutations were identified in 10 (8.9%) of 119 cancers initially diagnosed as endometrioid. However, 8 of these cancers were subsequently reclassified as serous or unspecified carcinoma after immunohistopathology review. Similarly, of the 4 (6.3%) of 63 cancers initially classified as clear cell identified as having a *BRCA* mutation, 3 were reclassified to be high-grade serous with focal clear cell differentiation (5).

Natural History of *BRCA*-associated Ovarian Cancer

Over a dozen studies have reported on differences in outcome between *BRCA*-associated and sporadic ovarian and fallopian tube cancers (8, 10–19). In the first study to address this issue, Rubin and colleagues, utilizing a case-control design, reported on 53 patients with a deleterious *BRCA1* mutation. They found

that patients with advanced stage *BRCA1*-associated disease had a median survival of 77 months compared to a median survival of 29 months in age, stage, and histologic subtype matched controls (10). In 2008, Chetrit and colleagues reported on an Israeli population-based series including data from 779 Jewish women with invasive epithelial ovarian cancer genotyped for the three Ashkenazi founder mutations. In this series, *BRCA* mutation status was associated with an increase in survival from 37.9 months to 53.7 months (15). Most recently, investigators from the Cancer Genome Atlas (TCGA) project reported that patients with stage II to IV high-grade serous ovarian or fallopian tube cancer and germline or sporadic mutations in *BRCA1* or *BRCA2* had improved outcome compared to patients without evidence of *BRCA* deficiency (median overall survival 66.5 vs. 41.9 months, $p = 0.0003$) (17). Interestingly, in this series, tumors associated with mutations in *BRCA1* or *BRCA2* also had improved outcome compared to patients with silencing of *BRCA1* due to methylation of the *BRCA1* promoter, suggesting that the mechanism of loss of *BRCA* function may be relevant to the biology and clinical behavior of these tumors.

Until recently, most studies examining the impact of *BRCA* mutations on outcome have analyzed carriers of *BRCA1* mutations and carriers of *BRCA2* mutations together. However, mutations in *BRCA1* and *BRCA2* cause related, but distinct, cancer susceptibility syndromes. Given this, it is possible that response to therapy and clinical outcome may differ between carriers of *BRCA1* mutations and carriers of *BRCA2* mutations. In the first study to examine this issue, Yang et al. reexamined data from the TCGA ovarian project. In this report, patients with *BRCA2*-associated ovarian cancer had markedly better outcome than those with *BRCA* wildtype tumors (HR = 0.33; 95% CI, 0.16–0.69). *BRCA1*-associated tumors also appeared to have a somewhat better outcome than *BRCA* wildtype tumors (HR = 0.76; 95% CI, 0.43–1.35), but this result did not reach statistical significance (20). In a single institution retrospective cohort from Memorial Sloan-Kettering Cancer Center, Hyman and colleagues reported on the outcome of 190 stage III to IV high-grade serous ovarian and fallopian tube cancer patients genotyped for *BRCA* mutations. Similar to the TCGA series, *BRCA2*-associated tumors were associated with significantly improved outcome compared to *BRCA* wildtype tumors (HR = 0.20; 95% CI, 0.06–0.65). In this study, a trend suggesting that *BRCA1*-associated tumors may have improved outcome compared to *BRCA* wildtype tumors (HR = 0.70; 95% CI, 0.36–1.38) was also noted (18). Most recently, Bolton et al. reported on a pooled series of 3,879 invasive epithelial ovarian cancers genotyped for *BRCA* mutations and found that in a model adjusted for age at diagnosis, stage, grade, and histology, both *BRCA2* (HR = 0.49; 95% CI, 0.39–0.61) and *BRCA1* (HR = 0.73; 95% CI, 0.64–0.84) had improved outcome compared to *BRCA* wildtype tumors. Tests of heterogeneity also demonstrated that hazard ratio for *BRCA2* mutation carriers was significantly different from the HR for *BRCA1* mutation carriers (19). Given the clear differences in the outcome between *BRCA* mutated and *BRCA* wildtype tumors, several authors have recommended that, at least for participants on clinical trials, we should obtain germline *BRCA* mutation status and stratify outcomes for the presence or absence of mutations (21, 22).

Therapeutic Implications

BRCA1 and *BRCA2* are known to be necessary for repair of double strand DNA breaks through homologous recombination (23, 24). Therefore, tumor cells from *BRCA*-associated ovarian cancers that have no working copy of either *BRCA1* or *BRCA2* are believed to be exquisitely sensitive to agents that induce double strand DNA breaks, such as platinum-based chemotherapy. While this mechanism likely explains at least some of the survival

advantage seen in *BRCA*-associated ovarian cancer, until recently knowledge of this information did not provide a new therapeutic opportunity as almost all patients with serous ovarian cancer receive platinum-based chemotherapeutics as part of first-line therapy. In 2005, however, 2 independent groups hypothesized that the *BRCA*-dependent homologous recombination pathway could be stressed by inhibiting poly (ADP-ribose) polymerase (PARP), an enzyme necessary for the repair of single strand DNA breaks (25, 26). If this enzyme (and repair of single strand DNA breaks) is inhibited during DNA replication, the advancing replication fork converts single strand DNA breaks into double strand breaks to be repaired by homologous recombination. In patients with a germline mutation in *BRCA1* or *BRCA2*, the single nonmutant allele is sufficient for allowing repair in non-tumor-associated cells. However, tumor associated cells have lost both working alleles of either *BRCA1* or *BRCA2* and therefore cannot utilize homologous recombination, forcing the cell to use error-prone nonhomologous end joining, which frequently leads to complex rearrangements and eventual apoptosis (27).

The first clinical data supporting the potential utility of PARP inhibitors in *BRCA*-associated tumors were published in 2009 (28). In this phase 1 trial, 60 patients, including 22 with either a documented *BRCA1* or *BRCA2* mutation, received increasing doses of a novel PARP inhibitor, olaparib. Radiologic response or stable disease was observed in 11 (9 ovarian and 2 breast cancer) of 19 patients with heavily pretreated *BRCA*-associated ovarian, breast or prostate cancer. This was followed shortly thereafter by a phase 2 study evaluating activity of olaparib at two dose levels in 57 patients with *BRCA*-associated pelvic serous cancer (29). In this series, 11 of 33 patients treated at the higher dose level had complete or partial response and an additional 12 patients had stable disease. Given the promising results of these first two trials, there are over a dozen ongoing or planned trials of PARP inhibitors in *BRCA*-associated pelvic serous cancer (30). Further, given that 9% to 15% of sporadic ovarian cancer has silencing of the homologous recombination pathway through methylation of the *BRCA1* promoter (17, 31, 32), PARP inhibitors are also being actively investigated for treatment of sporadic disease.

Genetic Counseling for Hereditary Breast and Ovarian Cancer Syndrome

Approximately 1 in 345 to 1 in 800 women have a *BRCA1* or *BRCA2* mutation associated with hereditary breast and ovarian cancer (33, 34). Hereditary breast and ovarian cancer syndrome is seen in all racial and ethnic groups. However, due to the phenomenon of genetic drift, several racial and ethnic groups have seen a marked increase in the population frequency of specific mutations, known as founder mutations. Best known of the founder mutations are the 185delAG and 5382insC mutations in *BRCA1* and the 6174delT mutation in *BRCA2* that are collectively found in 1 of 40 individuals of eastern European Jewish (Ashkenazi) heritage. Increased incidence of *BRCA* mutations has also been seen in individuals of Icelandic, Swedish, Dutch, Polish, French Canadian, and Hungarian descent.

The vast majority of deleterious mutations in *BRCA1* and *BRCA2* are nonsense mutations that lead to a premature stop codon and a truncated protein. While most protein-truncating mutations are detected by direct sequencing of *BRCA1* and *BRCA2*, approximately 6% to 18% of clearly deleterious mutations are caused by large genomic deletions or rearrangements that will not be picked up on direct sequencing and need to instead be screened for by methods such as MLPA (35–37). Additionally 6% to 17% of individuals undergoing direct sequencing of *BRCA1* or *BRCA2* will have a missense mutation identified that causes a single amino acid substitution in the protein (38). These missense mutations are termed variants of

uncertain significance, as it is frequently not possible to characterize whether the protein can tolerate the resulting amino acid substitution or if the substitution will cause abrogation of protein function.

Genetic counselors and other appropriately trained genetic professionals can assist in determining what are the most appropriate genetic tests for an individual patient. In addition, they can assist in interpreting the results in context with the family history. Further, the genetic counselor can assist in identifying who is the most appropriate individual to initiate genetic testing with, as in many families, it may be more informative to initiate testing in a relative other than the present individual. Lastly, genetic counselors can help identify other relatives who should be informed of a potential inherited risk (39) and can assist patients with plans for such communication.

CANCER RISKS ASSOCIATED WITH A *BRCA1* OR *BRCA2* MUTATION

For women with mutations in *BRCA1*, lifetime risks, through age 70, of pelvic (ovarian, fallopian tube, or primary peritoneal) cancer are on the order of 39% to 46%. For women with mutations in *BRCA2*, the lifetime risk of pelvic cancer is 12% to 20% (40, 41). The average age of diagnosis of *BRCA1*-associated pelvic cancers is 53, which is approximately 10 years earlier than the average age of diagnosis of sporadic ovarian or fallopian tube cancer. Interestingly, the average age of *BRCA2*-associated pelvic cancer is 60 to 62 years, which is no earlier than seen with sporadic disease (5, 8). When considering the timing of risk-reduction approaches, it is also important to know risks of cancer by the age of menopause. For women with *BRCA1* mutations, 10% to 21% will develop pelvic cancer by age 50, but only 2% to 3% of women with *BRCA2* mutations will develop pelvic cancer by the same age (41, 42).

Breast cancer risks are also markedly elevated for women with mutations in these genes, with risks of breast cancer approaching 65% to 74% by age 70 for both carriers of *BRCA1* and *BRCA2* mutations (40, 41). Breast cancer also occurs substantially earlier than seen in the general population, with 26% to 34% of carriers of either *BRCA1* or *BRCA2* mutations developing breast cancer by age 50 (40, 41, 43).

A number of genome-wide association studies (GWAS) have identified single nucleotide polymorphisms (SNPs) that modify breast and/or gynecologic cancer risk in the setting of a *BRCA1* or *BRCA2* mutation (44). Unfortunately, none of these markers, alone or in combination, has been shown to alter *BRCA*-associated cancer risk at a magnitude necessary to appreciably guide recommendations for risk-reduction strategies (45).

GUIDELINES FOR OFFERING GENETIC RISK ASSESSMENT FOR HEREDITARY BREAST AND OVARIAN CANCER SYNDROME

Several organizations have proposed guidelines for offering genetic risk assessment for hereditary breast and ovarian cancer syndrome. Likely, most relevant to the gynecologic oncologist are the guidelines jointly published by the American College of Obstetricians and Gynecologists (ACOG) and the Society of Gynecologic Oncology (SGO) (6) and those published by the National Comprehensive Cancer Network (NCCN) (7). Briefly, both of these guidelines state that hereditary cancer risk assessment is a process that: (a) should include assessment of risk, education, and counseling; (b) should be conducted by a physician,

genetic counselor, or other provider with experience in cancer genetics; and (c) may include genetic testing after appropriate counseling and consent is obtained.

Specifically, ACOG and SGO recommend that women with greater than approximately a 20% to 25% chance of having a *BRCA1* or *BRCA2* mutation be offered a genetic risk assessment. Further, they state that it is reasonable to offer genetic risk assessment to any woman who has greater than a 5% to 10% chance of having a *BRCA1* or *BRCA2* mutation. Specific constellations of personal and family history that meet this threshold are outlined in Table 3.2.

There are also several risk prediction models, such as BRCAPRO, BOADICEA, and IBIS, that can assist in predicting the likelihood of a patient having a mutation in *BRCA1* or *BRCA2*. Each of these models, however, has unique advantages and limitations, and selecting the appropriate model is generally best done with the assistance of a genetics professional.

Of particular note to physicians taking care of women with ovarian, fallopian tube, or primary peritoneal cancer, given 16% to 18% of all patients with serous ovarian cancer (including 8% to 10% of patients with no significant family history) will have a

Table 3.2 American College of Obstetricians and Gynecologists and Society of Gynecologic Oncologists Criteria for Offering Genetic Risk Assessment for Hereditary Breast and Ovarian Cancer Syndrome

Patients with greater than an approximate 20%–25% chance of having an inherited predisposition to breast cancer and ovarian cancer and for whom genetic risk assessment is recommended:

- Women with a personal history of both breast cancer and ovarian cancer^a
- Women with ovarian cancer^a and a close relative^b with ovarian cancer or premenopausal breast cancer
- Women with ovarian cancer^a who are of Ashkenazi Jewish ancestry
- Women with breast cancer at age 50 years or younger and a close relative^b with ovarian cancer^a or male breast cancer at any age
- Women of Ashkenazi Jewish ancestry in whom breast cancer was diagnosed at age 40 years or younger
- Women with a close relative^b with a known *BRCA1* or *BRCA2* mutation

Patients with greater than an approximate 5%–10% chance of having an inherited predisposition to breast cancer and ovarian cancer and for whom genetic risk assessment may be helpful:

- Women with breast cancer at age 40 years or younger
- Women with ovarian cancer, primary peritoneal cancer, or fallopian tube cancer of high-grade, serous histology at any age
- Women with bilateral breast cancer (particularly if the first case of breast cancer was diagnosed at age 50 years or younger)
- Women with breast cancer at age 50 years or younger and a close relative^b with breast cancer at age 50 years or younger
- Women of Ashkenazi Jewish ancestry with breast cancer at age 50 years or younger
- Women with breast cancer at any age and two or more close relatives^b with breast cancer at any age (particularly if at least one case of breast cancer was diagnosed at age 50 years or younger)
- Unaffected women with a close relative^b who meets one of the previous criteria

^aCancer of the peritoneum and fallopian tubes should be considered a part of the spectrum of the hereditary breast and ovarian cancer syndrome.

^bClose relative is defined as a first-degree relative (mother, sister, daughter) or second-degree relative (grandmother, granddaughter, aunt, niece).

Table 3.3 Risk-Reduction Recommendations for Carriers of *BRCA1* and *BRCA2* Mutations

Breast

- Annual mammography and annual breast MRI starting by age 30
- RRSO to reduce breast cancer risk between age 35 and 40 and when childbearing is complete
- Consider chemoprevention with tamoxifen, raloxifene, or an aromatase inhibitor
- Consider RRM

Ovary/Fallopian Tube

- RRSO to reduce ovarian and fallopian tube cancer risk between age 35 and 40 and when childbearing is complete
- Consider chemoprevention with oral contraceptives
- Consider ovarian cancer screening with q6 month transvaginal ultrasound and CA-125 from age 30–35 years until definitive risk-reduction with RRSO

RRSO, risk-reducing salpingo-oophorectomy; RRM, risk-reducing mastectomy.

deleterious *BRCA1* or *BRCA2* mutation (3–5), both the AGOG/SGO and NCCN practice guidelines state that it is reasonable to offer genetic risk assessment to any women with high-grade pelvic serous cancer if it will impact either her care or the care of her close family members (6, 7).

Screening and Prevention

For unaffected patients with a deleterious mutation in *BRCA1* or *BRCA2*, there are several options to reduce the risk of both gynecologic and breast cancer (Table 3.3).

Screening

Ovarian/Fallopian Tube Cancer

Screening for ovarian and fallopian tube cancer in the general population is not recommended. Reasons for this include the limited sensitivity and specificity of transvaginal ultrasound and CA-125 serum screening. Perhaps equally important is the low annual incidence of disease. In 2008, the annual incidence of ovarian cancer in women over 50 years was 1 in 2785 per year (46). Given this incidence, in order to achieve a positive predictive value of 10% (i.e., 1 ovarian cancer detected for every 10 surgeries) a screening approach must have a specificity of 99.7% in the setting of 100% sensitivity, which has not been achievable with current technologies. However, the annual incidence of ovarian cancer in women over 50 is 1.0% to 2.5% in *BRCA1* mutation carriers and 0.4% to 0.8% in *BRCA2* mutation carriers (40). In this setting, assuming an annual incidence of disease of 1%, a screening regimen with 100% sensitivity only needs a specificity of 91% to achieve a positive predictive value of 10%, which is potentially achievable with current imaging and serum screening approaches. In 2002, Scheuer and colleagues reported the experience of 62 women with a documented mutation in *BRCA1* or *BRCA2* who participated in ovarian cancer screening with twice-yearly transvaginal ultrasound and CA-125 (47). In this cohort, 5 of 7 ovarian and peritoneal cancers were screen detected, with 4 of these cancers being stage I or stage II. During the course of this study, however, another 5 of 55 women without cancer underwent exploratory surgery due to abnormal screening results. Together these results suggest that

twice-yearly transvaginal ultrasound and CA-125 screening in women with *BRCA1* or *BRCA2* mutations was associated with possibly acceptable 71% sensitivity, 91% specificity, and 50% positive predictive values. Importantly, a similar screening program at Cedars-Sinai Medical Center could not replicate these results. In this series of 213 women at increased risk of ovarian cancer, including 33 with mutations in *BRCA1* or *BRCA2*, only 4 of 8 invasive ovarian cancers were screen detected, and 3 of the 4 screen detected cancers were stage IIIc (48). In 2007, Hermesen and colleagues reported on the experience of 888 women with *BRCA1* or *BRCA2* mutations who participated in ovarian cancer screening with annual transvaginal ultrasound and CA-125 for a mean of 1.7 years between 1993 and 2005. In this study, 5 of the 10 incident invasive cancers presented as interval cancers with a normal screening result 3 to 10 months prior to diagnosis. Further, of the 5 screen detected cancers, 4 were stage III or IV, leading the authors to conclude that annual screening is not efficacious (49).

Of note, all of the studies to date commenting on ovarian cancer screening in *BRCA* mutation carriers have been retrospective case series and not rigorously conducted prospective screening trials. Two such prospective trials specifically targeting women at familial/inherited risk are either ongoing or recently completed, but not reported. In the recently completed Gynecologic Oncology Group study 0199, a prospective study of risk-reducing salpingo-oophorectomy and longitudinal CA-125 screening among women at increased genetic risk of ovarian cancer, participants elected either surveillance with annual transvaginal ultrasound and every 3 month CA-125 interrogated with the risk of ovarian cancer (ROCA) algorithm or risk-reducing salpingo-oophorectomy (RRSO) (50). All participants in the study were genotyped, and just under 400 of the approximately 1600 women who elected surveillance had a *BRCA* mutation. The study has completed data collection and is currently in analysis. The UK familial ovarian cancer screening study (UK FOCSS) is the other ongoing large-scale trial of women at familial or inherited risk (51). In this study, approximately 2350 women with greater than a 10% lifetime risk of ovarian cancer are being followed with annual transvaginal ultrasound and every 4 month CA-125 also interrogated with the ROCA algorithm. Study results are expected in 2013–2014.

Until results from GOG 199 and UK FOCSS are available, despite the absence of clear evidence for benefit, women with mutations in *BRCA1* or *BRCA2* likely should be recommended to consider ovarian cancer screening with transvaginal ultrasound and CA-125 determinations every 6 months from age 30 to 35 until they undergo definitive risk-reduction with risk-reducing salpingo-oophorectomy (7).

Breast Cancer

For patients with a deleterious mutation in *BRCA1* or *BRCA2*, annual mammography starting by age 30 is recommended (7, 52). However, several studies have suggested that mammography alone in women with *BRCA* mutations is inadequate. In 2001, Brekelmans and colleagues reported that 4 of 9 invasive breast cancers in 128 *BRCA* mutation carriers presented as palpable masses in the interval between screens (53). Similarly, in 2002, Scheuer et al. reported that 7 of 12 invasive breast cancers diagnosed in 251 *BRCA* mutation carriers undergoing mammographic screening presented as interval cancers (47). Due to the relatively low sensitivity of mammography, breast MRI has been investigated as a complimentary imaging modality. Three of the largest studies to date have shown a 71% to 78% sensitivity of breast MRI for *BRCA*-associated cancers compared to a 36% to 40% sensitivity for mammography (54). Further, in 2011, Warner and colleagues demonstrated that the addition of annual MRI to annual mammography led to a down staging of *BRCA*-associated breast cancers (adjusted hazard ratio for the

development of stage II to IV breast cancer associated with MRI screening = 0.30; 95% CI, 0.12–0.72) (55). Currently both the National Comprehensive Cancer Network and the American Cancer Society recommend the combination of annual mammography and annual breast MRI, beginning by age 30, for breast screening in women with *BRCA* mutations (7, 52).

Chemoprevention

Ovarian/Fallopian Tube Cancer

Multiple studies have suggested that use of oral contraceptives in the general population is associated with a substantial and long-lasting reduction in the risk of ovarian cancer (56). Given this, several authors have examined the impact of oral contraceptives on ovarian cancer risk in the setting of *BRCA1* or *BRCA2* mutations. In a recent meta-analysis of 5 case-control and retrospective cohort studies, Iodice and colleague found that ever use of oral contraceptives was associated with a significant reduction in ovarian cancer risk in both *BRCA1* (summary relative risk = 0.51; 95% CI, 0.40–0.65) and *BRCA2* (summary relative risk = 0.52; 95% CI, 0.31–0.87) mutation carriers (57). Further, longer use was associated with a greater risk-reduction, with a 36% risk reduction seen for each 10 years of use (summary relative risk = 0.64; 95% CI, 0.53–0.78).

When caring for women with *BRCA1* or *BRCA2* mutations, it is important, however, to evaluate for both breast and ovarian cancer risk, and the data regarding breast cancer risk has been somewhat more conflicting. Of 5 published studies addressing the impact of oral contraceptives on breast cancer risk in *BRCA1* mutation carriers, 3 suggested an increased risk of breast cancer with oral contraceptive use and 2 showed no increase in risk (58–62). Similarly in the 3 studies reporting on breast cancer risk with oral contraceptive use in *BRCA2* mutation carriers, 2 studies suggested an increased risk, and one study showed no increase in risk (58, 60, 62). In the Iodice meta-analysis, neither *BRCA1* (summary relative risk = 1.09; 95% CI, 0.77–1.54) nor *BRCA2* (summary relative risk = 1.15; 95% CI, 0.61–2.18) mutation carriers demonstrated a statistically significant increased risk of breast cancer with oral contraceptive use. However, oral contraceptive formulations used before 1975 were associated with an increased risk of breast cancer (summary relative risk = 1.47; 95% CI, 1.06–2.04). Given the data currently available, it likely still makes sense to counsel patients that oral contraceptives may be associated with some adverse impact on breast cancer risk. This potential risk, however, needs to be balanced against the risk of unintended pregnancy and the benefit of oral contraceptives on ovarian cancer risk.

Breast Cancer

The selective estrogen receptor modulators (SERMs), tamoxifen and raloxifene, in addition to the aromatase inhibitor exemestane have been studied in the general population as chemoprevention for breast cancer. Tamoxifen is the only one of these agents that has been studied in women with *BRCA* mutations. King and colleagues, in a reanalysis of the NSABP P-1 trial, found a suggestion that tamoxifen was associated with protection against *BRCA2* associated breast cancer (risk ratio, 0.38; 95% CI, 0.06–1.56) but not *BRCA1* associated breast cancer (risk ratio, 1.67; 95% CI, 0.32–10.70), though neither of these results reached statistical significance (63). It was speculated that the reason for this possible differential effect was the different estrogen receptor phenotypes of breast cancer seen between *BRCA1* and *BRCA2* mutations carriers. *BRCA2*-associated breast cancers are ER positive 65% to 80% of the time, as opposed to only 10% to 25% of *BRCA1*-associated breast cancers (64, 65). In 2000, Narod and colleagues looked at the impact of therapeutic tamoxifen on contralateral breast cancer risk. In

this study, tamoxifen appeared to be associated with a reduction of contralateral breast cancer risk in both *BRCA1* (odds ratio 0.38; 95% CI, 0.19–0.74) and *BRCA2* (odds ratio 0.63; 95% CI, 0.20–1.50) mutation carriers (66). Of potential significance, *BRCA1* mutation carriers who received tamoxifen in this study likely had ER positive disease. Weitzel et al. have subsequently demonstrated that, in women with *BRCA* mutations who develop contralateral breast cancer, the ER status of the second breast cancer is highly concordant with the ER status of the first breast cancer, suggesting that women with ER positive *BRCA1*-associated breast cancer are more likely to develop a second ER positive cancer and therefore more likely to benefit from hormonal chemoprevention (67).

Risk-Reducing Surgery

Salpingo-Oophorectomy

Impact on ovarian cancer risk. Two of the earliest studies to examine the impact of risk-reducing salpingo-oophorectomy (RRSO) on ovarian cancer risk were published in 2002. The first of these was a prospective cohort study from Memorial Sloan-Kettering Cancer Center. In this study, 170 women with a documented deleterious mutation in *BRCA1* or *BRCA2* elected either surveillance or RRSO. In this series, RRSO was associated with a 75% reduction in the subsequent risk of breast or *BRCA*-associated gynecologic cancer (HR = 0.25; 95% CI, 0.08–0.74) (68). When the impact of RRSO on gynecologic risk alone was examined, there was a suggestion of an approximately 85% reduction in gynecologic cancer risk (HR = 0.15; 95% CI, 0.02–1.31). Simultaneous with this report, a retrospective study from University of Pennsylvania found that RRSO was associated with an approximately 96% reduction in gynecologic cancer risk (HR = 0.04; 95% CI, 0.01–0.16) (69). However, a commentary from Klaren et al. pointed out that the retrospective study may have over-estimated the risk-reduction conferred (70). Since that time, several other studies have suggested that oophorectomy is associated with an 71% to 89% reduction in gynecologic cancer risk and a 2009 meta-analysis concluded that RRSO was associated with approximately an 79% reduction in risk of *BRCA*-associated gynecologic cancer (HR = 0.21; 95% CI, 0.12–0.39) (71).

The origin of peritoneal cancers after RRSO is not entirely clear. Some of these may represent recurrence of occult ovarian or tubal malignancies that were not recognized at time of initial pathologic evaluation, emphasizing the need for careful pathologic evaluation of the entire ovary and fallopian tube at time of RRSO. It has also been speculated that the peritoneal cancer can arise from exfoliated tubal cells (endosalpingiosis) that implant on the peritoneum and undergo malignant transformation in that location. Lastly, some authors have suggested that peritoneal malignancies can start exclusively in the peritoneum through müllerian metaplasia (72). Irrespective of the origin, it is important that patients undergoing RRSO be informed of the small possibility of primary peritoneal cancer occurring after the procedure.

Impact on breast cancer risk. In the first study examining the impact of RRSO on breast cancer risk, Rebbeck and colleagues found that RRSO in women with a *BRCA1* mutation was associated with a 47% reduction in *BRCA1*-associated breast cancer risk (HR = 0.53; 95% CI, 0.33–0.84) (73). In the prospective study by Kauff et al. reported in 2002, which examined both *BRCA1* and *BRCA2* mutation carriers, RRSO appeared to be associated with approximately a 68% reduction in breast cancer risk (HR = 0.32; 95% CI, 0.08–1.20) (68). In 2008, Kauff and Rebbeck pooled their updated prospective data and were able to report on 597 women with breast tissue at risk who had RRSO or surveillance and were prospectively followed for 2.8 years (74). When women with *BRCA1* and *BRCA2* mutations were examined together, RRSO was associated with a 47%

reduction in breast cancer risk (HR = 0.53; 95% CI, 0.29–0.96). However when *BRCA1* and *BRCA2* mutation carriers were examined separately, women with *BRCA2* mutations had a 72% reduction in breast cancer risk compared to women who left their ovaries *in situ* (HR = 0.28; 95% CI, 0.08–0.92). Women with *BRCA1* mutations appeared to have a 39% reduction in breast cancer risk (HR = 0.61; 95% CI, 0.30–1.22), but despite this being the largest prospective study to date, these results did not reach statistical significance. An exploratory analysis examining the impact of RRSO on breast cancer stratified for ER status was also performed. In this analysis, RRSO appeared to be profoundly protective against ER positive breast cancer (HR = 0.22; 95% CI, 0.05–1.05). Not unexpectedly, no impact against ER-negative breast cancer was noted (HR = 1.10; 95% CI, 0.48–2.51).

Impact on life expectancy. Domchek and colleagues reported on results of a prospective cohort study concluding that RRSO was associated with reduction in breast cancer-specific (HR = 0.44; 95% CI, 0.26–0.76), ovarian cancer-specific (HR = 0.21; 95% CI, 0.06–0.80), and all-cause mortality (HR = 0.40; 95% CI, 0.26–0.61) (75). While the effect of RRSO on mortality demonstrated by Domchek and colleagues is almost certainly present, there is a fair amount of instability in the estimates of the actual magnitude of this effect, as participants could be ascertained to this study as many as 20 years prior to the identification of *BRCA1* and *BRCA2*, but in many cases likely only underwent genotyping (and inclusion in the final analysis) if: (a) they lived long enough for clinical testing to become available and (b) they developed a cancer of interest.

Even given the limitations of this and other studies evaluating the efficacy of RRSO on subsequent cancer risk and mortality, for carriers of *BRCA1* and *BRCA2* mutations, RRSO remains the best available protection against pelvic serous cancer and should be strongly considered between 35 and 40 years of age and after childbearing is complete.

Technical considerations. Given that the ovaries and fallopian tubes are both at risk for malignant transformation, it is imperative that all of the ovaries and distal fallopian tube are removed at time of RRSO. In order to do this, it is necessary that the surgeon be able to enter the retroperitoneal space and ligate the infundibulopelvic ligament at least 2 cm from its insertion into the ovary.

Malignant cells leading to upstaging of disease have also been found in peritoneal cytology specimens from a number of women undergoing RRSO (76). Given these findings, washing likely should be performed at time of peritoneal entry in all women undergoing RRSO.

Additionally as 2% to 10% of RRSO specimens obtained from *BRCA* mutation carriers have an occult malignancy detected at time of pathologic review (77), it is essential that the entire ovary and fallopian tube be serially sectioned to minimize the possibility of a small invasive cancer going undetected (6). The fimbrial ends of the fallopian tubes are the most frequent site of occult invasive serous carcinomas (78–80), and these lesions are best visualized using the SEE-FIM (sectioning and extensively examining the fimbriated end) method (81). Briefly, in this method, the fimbriated portion of the fallopian tube is sectioned lengthwise (sagittally) in multiple planes to maximize exposure of the tubal plicae. When this method is utilized, serous tubal intraepithelial carcinoma (STIC), a putative precursor to invasive serous carcinoma, is also identified in as many as 5% to 8% of specimens obtained at time of RRSO in women with mutations in *BRCA1* or *BRCA2* (82, 83). Both the occult fallopian tube malignancies and STIC lesions typically overexpress mutant *TP53* protein (84). Patients in whom small high-grade invasive serous cancers are found incidentally at RRSO generally receive adjuvant chemotherapy. The role of chemotherapy in the management of serous tubal intraepithelial carcinoma (STIC) is less clear (76).

Timing of procedure. For most women with mutations in either *BRCA1* or *BRCA2*, RRSO should generally be considered between age 35 and 40 and when childbearing is complete (6). For women with *BRCA1* mutations, this age is recommended because only 2% to 3% of women with mutations in this gene will develop pelvic serous cancer by age 40, but 10% to 21% of *BRCA1* mutation carriers will develop pelvic serous cancer by age 50 years (40–42). For women with *BRCA2* mutations, the risk of pelvic serous cancer by age 50 is only 2% to 3%. However, women with *BRCA2* mutations who defer RRSO until the age of natural menopause, likely lose the profound reduction against *BRCA2*-associated breast cancer conferred by RRSO (74). For women with *BRCA2* mutations who have already had bilateral mastectomy and ovarian ablation is not being utilized as part of adjuvant therapy for a prior breast cancer, RRSO likely can be reasonably deferred until the mid-40s.

Mastectomy

Several studies have demonstrated that risk-reducing mastectomy (RRM) in women with *BRCA1* or *BRCA2* mutation is associated with an approximately 90% reduction in the risk of new breast cancer (85, 86). Importantly, the impact on life expectancy may be markedly less, as the majority of these cancers in women undergoing both mammography and breast MRI will be diagnosed at a curable stage. In a decision analysis by Kurian et al. RRM at age 40 (in addition to RRSO at age 40 and breast screening starting at age 25) only increased the probability of survival to age 70 from 74% to 77% in carriers of *BRCA1* mutations and from 80% to 82% in carriers of *BRCA2* mutations (87). Given these relatively small absolute changes in survival, either intensive breast screening or risk-reducing mastectomy is likely a reasonable option for a woman with a *BRCA1* or *BRCA2* mutation.

LYNCH SYNDROME

Epidemiology

Approximately 5% of endometrial cancer cases may be attributed to an inherited predisposition (88). Lynch syndrome, or hereditary nonpolyposis colorectal cancer (HNPCC) syndrome, accounts for the majority of these cases. Individuals with Lynch syndrome have a germline mutation in one of four genes in the DNA mismatch repair family; *MLH1*, *MSH2*, *MSH6*, or *PMS2*. While Lynch syndrome has historically been characterized by an increased risk for colorectal cancer, women with Lynch syndrome also have a substantial risk for endometrial cancer. The estimated risk for colon cancer in women is 40% to 60% and in men as high as 80% (89, 90). In women, the lifetime endometrial cancer risk is approximately 40% to 60%. In a study specifically looking at individuals with *MSH6* mutations, risk for endometrial cancer was 26% by age 70 and as high as 44% by 80 years of age, and lifetime risk of colon cancer was 10% by age 70 and 20% by age 80 (91). Women with Lynch syndrome also have an approximate 5% to 10% lifetime risk for developing ovarian cancer. Other cancers associated with Lynch syndrome include cancers of the stomach, small bowel, renal pelvis and ureter, and brain.

In the general population, Lynch syndrome occurs in about 1 in 600 to 1 in 3000 individuals (92, 93). In a population-based study on endometrial cancer patients, the incidence of Lynch syndrome was 2.3%, which is similar to the 2.2% incidence of Lynch syndrome among colon cancer patients (94). For women with endometrial cancer under the age of 50, the proportion with Lynch syndrome increases to 5% to 9% (95–97). The mean age of diagnosis for endometrial cancer in women with Lynch syndrome is 47 years, which is substantially lower than the mean age of diagnosis of endometrial cancer in the general population, 60 years. Women with Lynch syndrome are at increased risk of

developing synchronous or metachronous cancers. In a study that examined 101 women with Lynch syndrome who had developed both GI cancer and gynecologic cancer, 51% presented, at a median age of 44, with their gynecologic cancer first, and 49% presented with their GI cancer first (98).

Prior to the discovery of the genes responsible for Lynch syndrome, criteria were formulated to identify families with Lynch syndrome for research studies. The initial Amsterdam I criteria focused on colon cancer and were subsequently revised (Amsterdam II), to include all Lynch syndrome-associated cancers. The criteria include: (a) three or more relatives with Lynch syndrome-associated cancers, (b) two affected relatives in successive generations, (c) one affected relative is a first-degree relative of the other two, and (d) one or more relatives with Lynch syndrome-associated cancer diagnosed before the age of 50 years.

Pathology

Unlike the ovarian cancers associated with *BRCA1* and *BRCA2* mutations, the endometrial cancers associated with Lynch syndrome span a broader spectrum. In a study by Broaddus et al., 43 of 50 (86%) endometrial cancers were endometrioid histology, with the remainder being papillary serous carcinoma, clear cell carcinoma, and malignant mixed müllerian tumors (99). Interestingly, all of the nonendometrioid tumors in this study occurred in patients with *MSH2* mutations. Among all of the patients with Lynch syndrome, 78% were diagnosed at stage I, 10% at stage II, and 12% at stage III or IV. Lymphovascular space involvement was noted in 24% of the cases, and 26% had deep myometrial involvement that was defined as invasion greater than 50%. Endometrial cancers that arise in the lower uterine segment are rare in the general population, but are seen more frequently in women with Lynch syndrome. In a study by Westin et al., almost one third of patients with endometrial cancers arising in the lower uterine segment were suspected to have Lynch syndrome, based on tumor studies or germline testing (100). This characteristic phenotype is similar to the increased proportion of right-sided colon cancers seen in individuals with Lynch syndrome. Other pathologic features that have been seen more frequently in Lynch syndrome-associated colon cancers, including poor tumor differentiation and tumor infiltrating lymphocytes, have not been seen consistently in Lynch syndrome associated endometrial cancers.

The ovarian cancers seen in Lynch syndrome also have a different stage and histology spectrum from that seen in women with sporadic disease. In a recent series, 22 (47%) of 47 Lynch-associated epithelial ovarian cancers presented at stage I. Further, serous cancers were underrepresented in this series, accounting for only 28% of tumors. Endometrioid, clear cell, and mucinous histologies were seen in 35%, 17%, and 5%, respectively (101).

Genetic Risk Assessment for Lynch Syndrome

For gynecologic oncologists, identifying Lynch syndrome in a patient with endometrial cancer has important implications for both the woman with cancer and for her family members. Individuals with Lynch syndrome are at significant lifetime risk of developing a second primary malignancy. Therefore, when an endometrial cancer patient is identified as having Lynch syndrome, appropriate colon cancer screening can be initiated. In addition, if a specific mutation in one of the DNA mismatch repair genes is identified in the endometrial cancer patient, her family members can undergo targeted predictive genetic testing for the same mutation.

Historically, guidelines to assist physicians in identifying patients with Lynch syndrome have focused on colon cancer patients. The Bethesda criteria, which were established in 1997

and revised in 2004, assist physicians in identifying colon cancer patients who may have Lynch syndrome (102). However, it has become increasingly clear that Lynch syndrome patients often present with endometrial or ovarian cancer as their first cancer. In 2007, the Society of Gynecologic Oncologists provided guidelines to assist in identifying patients for whom genetic risk assessment may be helpful (Table 3.4). They specifically recommended that women who have a greater than approximately 20% to 25% chance of having Lynch syndrome be offered risk assessment (103). Individuals meeting this criteria include women with endometrial cancer who fulfill the Amsterdam criteria; patients with synchronous or metachronous endometrial and colorectal cancer whose first cancer was diagnosed at less than age 50, patients with synchronous or metachronous ovarian and colorectal cancer whose first cancer diagnosed at

Table 3.4 Society of Gynecologic Oncologists Criteria for Offering Genetic Risk Assessment for Lynch Syndrome

Patients with greater than approximately 20%–25% chance of having Lynch syndrome and for whom genetic risk assessment is recommended:

- Patients with endometrial or colorectal cancer who meet the revised Amsterdam criteria as listed below:
 - At least three relatives with a sentinel Lynch-associated cancer (colorectal cancer, cancer of the endometrium, small bowel, ureter, or renal pelvis) in one lineage;
 - One affected individual should be a first-degree relative of the other two;
 - At least 2 successive generations should be affected;
 - At least 1 Lynch-associated cancer should be diagnosed before age 50.
- Patients with synchronous or metachronous endometrial and colorectal cancer with the first cancer diagnosed prior to age 50
- Patients with synchronous or metachronous ovarian and colorectal cancer with the first cancer diagnosed prior to age 50
- Patients with colorectal or endometrial cancer with evidence of a mismatch repair defect (i.e., microsatellite instability (MSI) or immunohistochemical loss of expression of MLH1, MSH2, MSH6, or PMS2)
- Patients with a first- or second-degree relative with a known mismatch repair gene mutation

Patients with greater than approximately 5%–10% chance of having Lynch syndrome and for whom genetic risk assessment may be helpful:

- Patients with endometrial or colorectal cancer diagnosed prior to age 50
- Patient with endometrial or ovarian cancer with a synchronous or metachronous colon or other Lynch syndrome–associated tumor^a at any age
- Patients with endometrial or colorectal cancer and a first-degree relative with a Lynch syndrome–associated tumor^a diagnosed prior to age 50
- Patients with colorectal or endometrial cancer diagnosed at any age with two or more first- or second-degree-relatives^b with Lynch syndrome–associated tumors^a, regardless of age
- Patients with a first or second-degree relative^b that meets the above criteria

^aLynch-associated tumors include colorectal, endometrial, stomach, ovarian, pancreas, ureter and renal pelvis, biliary tract, and brain (usually glioblastoma as seen in Turcot syndrome) tumors, sebaceous gland adenomas and keratoacanthomas in Muir-Torre syndrome, and carcinoma of the small bowel.
^bFirst and second-degree relatives are parents, siblings, children, aunts, uncles, nieces, nephews, grandparents and grandchildren.

Source: Adapted from Lancaster JM, Powell CB, Kauff ND, et al. Society of Gynecologic Oncologists Education Committee statement on risk assessment for inherited gynecologic cancer predispositions. *Gynecol Oncol* 2007;107: 159–162, with permission¹⁰³

less than 50, patients with endometrial cancer with molecular or immunohistochemical evidence of a mismatch repair defect, and patients with a first or second degree relative with a known mismatch repair gene mutation. In addition, the Society of Gynecologic Oncologists guidelines also identified a category of patients who have a 5% to 10% risk for Lynch syndrome and for whom genetic risk assessment may be helpful. These include patients with endometrial cancer diagnosed at less than age 50, patients with an endometrial or ovarian cancer and a synchronous or metachronous colon cancer at any age, and patients with endometrial cancer diagnosed at any age with 2 or more first- or second-degree relatives with Lynch syndrome–associated cancers, regardless of age.

While family history remains an important component in identifying individuals who may benefit from genetic risk assessment for Lynch syndrome, tumor testing for evidence of mismatch repair defects is an intermediate step that can be useful for triaging which patients may be at risk for having one of the germline DNA mismatch repair mutations (104, 105). These tumor tests include immunohistochemistry for 1 of the 4 mismatch repair proteins (*MLH1*, *MSH2*, *MSH6*, and *PMS2*) and microsatellite instability (MSI) analysis. Both of these studies can be performed on formalin-fixed, paraffin-embedded tissues and can be a first step in the evaluation of Lynch syndrome in a patient with endometrial cancer. Although it has been suggested that it may be cost-effective to do these tests on all endometrial cancers (106), this approach has not yet been widely adopted. For immunohistochemistry tests, the absence of a specific mismatch repair protein in the tumor is considered abnormal. For example, a tumor may demonstrate loss of staining of *MSH2* with normal staining of *MLH1*, *MSH6*, and *PMS2*. The loss of staining of *MSH2* in the tumor reflects that both copies of the gene are nonfunctional and suggests that the woman has a likely *MSH2* germline mutation.

For MSI testing, both tumor and normal tissues are required. MSI testing reflects the tumor phenotype of deficient DNA repair. When a tumor has deficient DNA repair capability, multiple mistakes occur in the DNA in both coding and noncoding regions. These mistakes are especially common in regions of mononucleotide and dinucleotide repeats, such as CCCCCC or CGCGCG. The National Cancer Institute has identified 7 of these sites on the genome that can be examined for microsatellite instability testing (BAT25, BAT26, BAT40, D2S123, D5S346, D173250, and TGF-BR2). Tumors with allelic shift in 2 or more microsatellites in the panel are considered MSI-high. Tumors with allelic shift in only one microsatellite are considered MSI-low. Tumors with no allelic shift in all 7 microsatellites are considered microsatellite-stable. For MSI-high tumors with loss of *MLH1* by IHC, methylation-specific PCR for *MLH1* proximal promoter region –248 to –178 is performed to detect possible methylation of the *MLH1* promoter. When methylation is present, the patient most likely has a sporadic carcinoma rather than a Lynch syndrome–associated cancer (*MLH1* promoter methylation is discussed in more detail in Chapter 2).

Immunohistochemistry can also direct genetic testing specifically for which one of the four DNA mismatch repair genes should be tested. For example, in individuals who have lost *MSH2* by immunohistochemistry, genetic testing can be initiated specifically for the *MSH2* gene. Once a specific germline mutation has been identified, at-risk family members can be tested for the same germline mutation, but at a substantially reduced cost.

Screening and Prevention

Screening and Chemoprevention

Guidelines for screening and prevention of Lynch syndrome–associated cancers have been published and should be reviewed with patients when the diagnosis of Lynch syndrome is made

(107, 108) (Table 3.5). Colon cancer screening is recommended in individuals with Lynch syndrome every 1 to 2 years starting at the age of 20 to 25 years (or 30 years in patients with known *MSH6* mutations). Jarvinen et al. reported a reduction in the incidence of invasive colorectal cancer from 16% to 6% ($p = 0.014$), with a relative risk of death of 0.34 (95% CI, 0.17–0.68) in individuals with Lynch syndrome who received colonoscopy or sigmoidoscopy and barium enema every 3 years compared to those who received no routine screening (109).

In contrast to colon cancer screening, there are no proven screening strategies for the early detection of endometrial or ovarian cancer in women with Lynch syndrome. Two European studies reported a high false-positive rate and poor efficacy using measurement of endometrial stripe by transvaginal ultrasound as an endometrial cancer screening tool (110, 111). More promising, two studies have reported identification of premalignant lesions and endometrial cancers in asymptomatic women with Lynch syndrome using office endometrial biopsy as a screening strategy (112, 113). One of these studies included 175 women with known *MLH1*, *MSH2*, or *MSH6* gene mutations and reported a stage migration with 7% of women in the surveillance group presenting with Stage III/IV disease versus 17% of women who presented symptomatically (112). The second study on 100 women from Lynch kindreds reported that routine endometrial sampling resulted in a significantly higher rate of malignancies and premalignancies compared with prior historical controls in which routine annual endometrial sampling was not performed (6.3% vs. 1.4%, $p = 0.026$) (113). No studies have examined the mortality impact of annual endometrial sampling in women with Lynch syndrome. Consensus guidelines currently recommend consideration of annual surveillance with endometrial biopsy for evaluation of the uterus and transvaginal ultrasound for evaluation of the ovaries (108). It is important to emphasize to the patient that data to support these recommendations are limited. A study by Huang et al. demonstrated the feasibility and acceptability of performing the annual endometrial biopsy, while the patient is sedated for the screening colonoscopy in women with Lynch syndrome (114). There was a substantial

reduction in reported pain when the procedures were done concurrently under sedation.

In the general population, progestin-based oral contraceptives have been shown to decrease endometrial and ovarian cancer risk by 50% (56, 115, 116). Progestin therapy is also effective at reversing complex atypical hyperplasia and early endometrial cancer (117, 118). While there are no epidemiologic data to support the role of progestins or progestin-based oral contraceptives as chemoprevention in women known to have Lynch syndrome, a short-term biomarker study demonstrated a significant decrease in endometrial proliferation using both 150 mg depo medroxyprogesterone acetate and 30 μ g ethinyl estradiol/0.3 mg norgestrel oral contraceptive pill (119). An ongoing trial is examining the use of the levo-norgestrel IUD as a chemopreventive in women with Lynch syndrome.

Risk-Reducing Surgery

Risk-reducing hysterectomy and salpingo-oophorectomy are reasonable options for prevention of endometrial and ovarian cancer in women with Lynch syndrome. A multi-institutional retrospective study of women with Lynch syndrome demonstrated that the incidence of endometrial cancer fell from 33% to 0% in women who underwent hysterectomy, and the incidence of ovarian cancer fell from 5.4% to 0% in women who underwent salpingo-oophorectomy (120). The risk of primary peritoneal cancer after oophorectomy in women with Lynch syndrome is unclear, although one case report has been published (121). It is also important to note that occult endometrial cancers have been found in asymptomatic women at the time of risk-reducing hysterectomy and salpingo-oophorectomy (122–124).

Women with Lynch syndrome should be counseled that the estimated risk for endometrial cancer by age 40 does not exceed 2% and the estimated risk of ovarian cancer by age 40 does not exceed 1% (90). Therefore, women with Lynch syndrome can complete childbearing prior to consideration of risk-reducing surgery. In addition, there does not appear to be a contraindication to estrogen replacement therapy after risk-reducing surgery. Two studies have performed cost-effectiveness analyses of options for gynecologic risk reduction in women with Lynch syndrome (125, 126). Both studies found that risk-reducing hysterectomy and salpingo-oophorectomy led to both the lowest cost and the greatest increase in quality-adjusted life years.

For patients undergoing colonic resection for a Lynch-associated colorectal cancer, it may be reasonable to discuss concomitant hysterectomy with BSO. However, for premenopausal patients who are diagnosed with Lynch syndrome at the same time as their colorectal cancer, there can be substantial fertility and psychosocial issues associated with this approach.

Table 3.5 Risk-Reduction Recommendations for Women with Lynch Syndrome

Gastrointestinal

- Colonoscopy every 1–2 years beginning at age 20–25 (or age 30 for women with *MSH6* mutations)
- Consider esophagogastroduodenoscopy (EGD) every 2–3 years beginning at age 30–35
- Consider capsule endoscopy every 2–3 years beginning at age 30–35
- Consider chemoprevention with aspirin or NSAIDs

Gynecologic

- Patients should be aware that abnormal vaginal bleeding warrants evaluation
- Consider screening with annual endometrial biopsy and transvaginal ultrasound beginning at age 30
- Consider chemoprevention with oral contraceptives or progestins
- Consider risk-reducing hysterectomy with bilateral salpingo-oophorectomy between age 35 and 40 and when childbearing is complete

Urologic

- Consider annual urinalysis starting at age 25–30

OTHER INHERITED SYNDROMES WITH A GYNECOLOGIC CANCER COMPONENT

Cowden Syndrome, Li-Fraumeni syndrome, and Peutz-Jeghers syndrome are rare autosomal dominant inherited cancer susceptibility syndromes that include gynecologic cancers as part of their cancer spectrum.

Cowden Syndrome

Cowden syndrome is caused by germline mutations in the *PTEN* gene. Individuals with Cowden Syndrome are at increased risk for both benign and malignant processes. These include gastrointestinal polyps, thyroid disease, benign breast

Adapted from Lindor NM, Petersen GM, Hadley DW, et al. Recommendations for the care of individuals with an inherited predisposition to Lynch syndrome: a systematic review. *JAMA* 2006;296(12): 1507–1517 and National Comprehensive Cancer Network: NCCN Clinical Practice Guidelines in Oncology—Colorectal Cancer Screening. Version 2.2012. <http://www.nccn.org>. 2012.

disease, mucocutaneous lesions, as well as breast, thyroid, and endometrial cancer (127). The lifetime risk of endometrial cancer in a woman with Cowden's syndrome has been estimated to be 5% to 28% (128, 129). Current NCCN guidelines recommend observation for and prompt evaluation of abnormal uterine bleeding (7). Screening with endometrial biopsies and/or ultrasound measurement of the endometrial stripe is being evaluated in the context of ongoing research studies.

Li-Fraumeni Syndrome

Li-Fraumeni syndrome is caused by germline mutations in *TP53* and is characterized by early-onset breast cancer, soft-tissue and bone sarcomas, adrenal cortical tumors, and brain tumors (130). Although not a major cancer risk in individuals with Li-Fraumeni syndrome, cases of ovarian cancer have been reported. While screening breast MRI is recommended beginning at age 20 to 25, there are no current screening recommendations for gynecologic cancers in women with Li-Fraumeni syndrome (7, 131).

Peutz-Jeghers Syndrome

Peutz-Jeghers syndrome is caused by germline mutations in *STK11*. Peutz-Jeghers is generally characterized by multiple gastro-intestinal polyps and pigmented lesions on the lips and buccal mucosa. Women with this syndrome also have a markedly increased risk for gastrointestinal and breast malignancies (132). Gynecologic cancers associated with this syndrome include sex cord-stromal tumors with annular tubules (SCTAT) of the ovary and adenoma malignum of the cervix (133). SCTAT are typically benign and bilateral. Adenoma malignum of the cervix is a rare and aggressive neoplasm that can also be seen in Peutz-Jeghers syndrome. It is often difficult to diagnose both clinically and histologically. On imaging, the tumor appears as a multicystic endocervical mass. Histologically, the tumor appears well differentiated, but the natural history can be aggressive. Due to the rarity of the syndrome and the gynecologic cancers, it is unclear whether women with Peutz-Jeghers should be screened. Yearly pelvic exam and pap smear beginning at age 25 have been recommended. However, the role of pelvic imaging is unclear (134).

Invasion, Metastasis, and Angiogenesis

SHARON ROMANO-FITZGERALD ■ ALEXANDRE BUCKLEY
DE MERITENS ■ ANGELES ALVAREZ SECORD ■ ELISE C. KOHN

INTRODUCTION

Gynecologic cancers are potentially curable if diagnosed at an early stage, when the tumor remains confined to the primary organ; survival is compromised by the dissemination or metastasis of the disease to vital organs at more advanced stages. In ovarian cancer, the leading cause of death for gynecologic malignancies in the United States, survival rates decrease dramatically with advanced disease presentation. The 5-year relative survival rate in advanced ovarian cancer with spread outside the pelvis is 26.9%, in contrast to a rate of 91.5% in stage I disease. A similar pattern is seen in cancers of the cervix and uterine corpus, with 5-year relative survival rates for localized disease of 90.7% and 95.4%, respectively; for distant disease, the rates are 16.2% and 16.4%, respectively (Howlader, et al: http://seer.cancer.gov/csr/1975_2009_pops09). The progression from hyperplasia to carcinoma *in situ* to invasive and then metastatic cancer determines staging and prognosis (Fig. 4.1).

Metastasis, the spread of malignant cells from the primary tumor to other sites, requires tumor cells detach from their primary mass, invade the stroma, travel to a secondary site via the lymphatic and/or the vascular system, extravasate and migrate within the secondary stroma, and grow (1). Tumor cells must also interact closely with elements in their microenvironment and

communicate with them to successfully achieve metastasis (2,3). The peritoneum, omentum, and mesenteric serosa are permissive environments to which the tumor cells attach and grow, co-opting support cells and vasculature to sustain their survival and growth. Through overcoming anoikis, a form of apoptosis triggered by loss of attachment to the solid extracellular matrix (ECM) substratum, cancer cells survive in the intra-abdominal milieu and in the peritoneal fluid or ascites (4,5).

The endothelium is the cellular lining on the luminal side of blood vessels, which serve as the first docking interface for circulating tumor cells. The endothelium creates a semi-permeable barrier sitting over its basement membrane; together they control blood–tissue exchanges of fluids, nutrients, and metabolic wastes, while preventing access to and from the tissues for pathogens and tumor cells (6). Altering endothelial cell–cell adhesion alters this critical endothelial barrier function. Loss of cell–cell adhesion allows endothelial cells to constrict in response to noxious stimuli. Constriction permits retraction, leaving acellular regions of sub-endothelial basement membrane exposed. Tumor cells attach to and degrade these denuded matrix regions (7).

The primary tumor and metastatic sites also have a high metabolic demand requiring adequate blood supply, absent which, tumor cells survive by autophagy, internal protein degradation, and recycling (8,9). Angiogenesis, the formation of new vessels, is necessary both as a route for metastasis and to provide the metastatic sites with exogenous nutrients to support tumor

FIGURE 4.1. Paradigm of cancer progression. Progression from the earliest detectable event of complex hyperplasia to overt invasive and metastatic malignancy is over a decade for endometrial and cervical cancers. The new recognition of the tubal epithelium as the source for type 2 high-grade serous ovarian cancer leaves this time frame still undetermined. Where identified early, each of these cancers has a high cure rate and long overall survival. However, when identified at or beyond the stage of microinvasion, progressive disease and death from disease is common.

growth (1). Many proangiogenic and antiangiogenic factors are secreted into and by elements of the tumor microenvironment leading to new vasculature that supports tumor survival and progression (10). Invasion, angiogenesis, and metastasis are thus orchestrated within the tumor microenvironment through a dynamic interaction between the tumor cells, the ECM, stromal and immunologic cells, and secreted chemokines and growth factors (1,2). Cancer cells use normal cellular processes to survive and progress, albeit without the tight regulation seen in normal cells. Tumor cells adapt in response to environmental and cellular stress and upregulate different mechanisms as cell migration, angiogenesis, autophagy, and apoptosis for their survival (11).

PATTERNS OF SPREAD

Gynecological cancers are able to disseminate in a multitude of ways (Fig. 4.2), and morbidity and mortality are associated with extent of tumor spread, invasion, and metastasis. The classical mechanism of dissemination of solid tumors is invasion of surrounding tissues followed by subsequent hematogenous and/or lymphatic spread. Endometrial and cervical cancers tend to be found as solid disease that extends locally and/or spreads in a defined pattern through the lymphatics, and later through

the vasculature. Their staging is dependent on the extent of local structural invasion and/or lymph node status. In most solid tumors, such as these gynecologic cancers and breast cancer, death is usually the consequence of distant metastasis.

In ovarian and fallopian tube carcinomas, primary and early dissemination occurs through the shedding of tumor cells (2,12) directly into the abdominal cavity; these cells then spread via the passive movement of peritoneal fluid. Cancer cells in the peritoneal fluid or ascites survive in this hypoxic, structure-free milieu by resisting anoikis (13). Attachment to serosa or peritoneum precedes local invasion and secondary metastasis; the presence of lymph node disease in ovarian cancer indicates invasion, involvement of the next step after shedding. Vascular dissemination for these and peritoneal serous cancers is a late event leading to parenchymal organ metastasis. Therefore, the ability of a tumor to spread or shed is not an isolated process; it requires upregulation of survival mechanisms as well as close interaction with other cells and the local environmental milieu (2,14).

MICROENVIRONMENT

The genetic and phenotypic make-up of a tumor is a major determinant of its metastatic efficiency, and a receptive microenvironment is a prerequisite for successful tumor growth (15,16).

FIGURE 4.2. Ovarian cancer: shedding and spreading. The primary ovarian tumor located in the ovarian stroma metastasizes in two different ways. The first mechanism **(A)**, occurring early is by shedding cancer cells into the peritoneal cavity after reaching the ovarian surface; the second mechanism **(B)**, later occurring, is invasion into surrounding tissues. Cells shed in the peritoneal fluid, form spheroids that have acquired mechanisms to resist anoikis. These spheroids will then implant on the peritoneal mesothelial surface and cause stromal activation with desmoplasia, inflammation, and angiogenesis. ECM: extra-cellular matrix; FGF: fibroblast growth factor; MMPs: matrix metalloproteinases; VEGF: vascular endothelial growth factor.

Sir James Paget stated in 1889 that the microenvironment of each organ, *the soil*, influences the survival and growth of tumor cells, *the seed* (16,17). Multiple overlapping signal and adhesion networks cooperate to enable molecular and structural remodeling of tissues that overall support tumor invasion, growth, and metastatic dissemination. Cellular behavior and the activation or inactivation of genes are influenced heavily by the microenvironment (1,14). Gene expression profiling and proteomics have identified a variety of factors that are upregulated in the microenvironment of gynecological tumors. This reinforces the idea that complex interplay of molecules and signals are needed for tumor sustainability. Additionally, the microenvironment has a plasticity that allows participating elements to vary throughout the events of cancer progression. The flexibility of the microenvironment supports survival of the tumor cells and their ability to withstand an otherwise harsh environment with elements of hypoxia, metabolic stress, and inflammation (3).

Inflammation/Priming

Inflammation may promote carcinogenesis and dissemination through several mechanisms affecting growth, invasion, angiogenesis, and neoplastic changes (18). These inflammatory mechanisms include but are not limited to the production of reactive oxygen species and free radicals that directly damage DNA and proteins, and production of proinflammatory/proangiogenic molecules, such as cytokines, tumor necrosis factor- α (TNF α), and interleukins (18). Various immune cells have been found as part of the tumor inflammatory infiltrate. Among them, macrophages play a central role in most solid malignancies (19). Some T cells facilitate invasion of tumor cells by altering macrophages into a more invasive phenotype in an IL-4 dependent manner supporting the idea that inflammation mediators play a role in cancer progression (20). Inflammatory factors can also increase inflammatory enzymes such as cyclooxygenase-2, which lead to the production of other proinflammatory products (21). Studies have shown an inverse relationship between nonsteroidal anti-inflammatory drugs and reduced risk of ovarian and cervical cancers (18,22,23).

Multiple causes of local inflammation including exposure to talc, asbestos, and presence of endometriosis and recurrent pelvic inflammatory disease have been identified as putative risk factors for ovarian cancer (24,25). Cervical cancer studies have shown that, in addition to HPV, other sexually transmitted infections such as herpes simplex virus and Chlamydia are associated with increased risk of carcinoma *in situ* and/or invasive cervical cancer (26). It is believed that the subsequent inflammatory response and micro-ulceration that follows these non-HPV infections increase the epithelial cell repair and proliferation, permitting or promoting transformation (27). One study reported that cervical inflammation, independent of infections, was associated with squamous metaplasia of the cervix, a precursor to malignancy (28).

The menstrual cycle is a physiologic inflammatory process. The endometrium is a dynamic cyclic organ with cycles of growth, remodeling, differentiation, and angiogenesis. Estrogen drives these changes by facilitating the release of inflammatory mediators from the epithelial, stromal, and vascular cells of the endometrium (18,29). Increased exposure of the endometrium to inflammation occurs by the same mechanisms that are considered risk factors for endometrial cancer. These endometrial risk factors include unopposed estrogen use, polycystic ovarian syndrome, excessive menstruation, obesity, and diabetes. Therefore, it is believed that inflammation alone or in conjunction with estrogen plays a role in the development of endometrial cancer (18).

Tumor cells coopt normal host cells and rely on communication with other cell types including macrophages, T cells and

other immune cells, endothelial cells, and stromal cells (20). Cancer cells may also cause transdifferentiation of host cells. Tumor-released inflammatory cytokines act on local cells to convert host fibroblasts into cancer-associated fibroblasts (CAFs). Activated CAFs help promote ovarian and endometrial tumor cell invasion through activation and production of growth factors, such as tumor growth factor- β (TGF β) and chemokines (14,30,31). CAFs are part of a paracrine loop that increases cancer cell invasion (30). Furthermore, there are multiple cell interactions and stimulatory and inhibitory factors leading to feedback loops that help amplify and sustain the tumor cells in this environment (32).

Communication between tumor cells and host cells at distant tissue sites via circulating factors, immune cells, chemokines, and growth factors can prime and direct the location of future metastatic tumor growth (33). Tumor-associated macrophages, recruited by the presence of the tumor, alter the local chemokine balance resulting in directed migration, proliferation, and differentiation of the vascular cell network and inflammatory infiltrate of the tumor microenvironment. This functions to support tumor growth, both at the primary tumor and upon metastasis (20). Shibuya and colleagues demonstrated enhanced matrix metalloproteinase (MMP)-9, a protease that breaks down the ECM, was measured in the lung preceding demonstrable tumor cell metastasis, suggesting that this was induced by signals from the distant primary tumor in a paracrine fashion (34). Therefore, the role of the immune system in cancer is complex and supports the idea that a permissive microenvironment is critical for the initiation of tumor growth and establishment of metastatic lesions at secondary sites (15).

Chemokines/Growth Factors

Chemotactic cytokines, known as chemokines, are small, secreted proteins or peptides that help regulate cell motility. Their primary function is chemoattraction and activation of leukocytes that then recruit other immune and/or inflammatory cells from the blood to the affected site. These proteins are implicated in initiation and progression of cancer (35). Cancer cells and many cells in the malignant microenvironment produce and/or respond to chemokines in an autocrine or paracrine manner via chemotaxis, migration up a concentration gradient, or chemokinesis, migration within a chemoattractant milieu (32). Chemokines and their receptors act at many stages of tumor progression, ranging from cell transformation, angiogenesis promotion, to tumor and supporting cell growth. Tumor cell passage through the ECM, the vasculature, and/or lymphatics is mediated by chemokines (35). Growth factors, differentiated from chemokines by their definition initially as growth promoters for epithelial not inflammatory cells, also play a role in tumor ascites formation, motility, invasion, and migration (24).

One of many important chemokine pairs is the receptor CXCR4 and its ligand CXCL12. Together, they activate signaling pathways that enhance proliferation, migration, angiogenesis, and invasion of gynecologic cancers (36,38). Normal ovaries express very little CXCR4; whereas, it is expressed in approximately 60% of ovarian cancers. CXCL12 is expressed in more than 90% of ovarian cancers (37). CXCR4 was found to be the only receptor of 14 chemokine receptors studied to be expressed in ovarian cancer cells (38). Its expression is an independent negative prognostic factor for progression-free and overall survival in ovarian cancer (39). AMD3100, a CXCR4 inhibitor, blocked CXCL12-stimulated migration of ovarian cancer cells *in vitro* (40,41). Blockade of CXCR4/CXCL12 activation led to reduced tumor growth and prolonged survival in ovarian cancer xenografts (37).

Interleukins-8 (IL-8) and -6 (IL-6) are multifunctional chemokines that are secreted by multiple cell types, including monocytes,

neutrophils, endothelial and mesothelial cells, and tumor cells. They are usually activated during an inflammatory response and function to recruit other immune cells to the affected site (42). Recent studies have shown that tumor progression and metastasis are associated with overexpression of these chemokines (43,44). Ovarian cyst fluid, effusions, blood, and tumor tissue have elevated IL-8 and IL-6 expression, correlated with poor overall survival (42,43). Bellone et al. demonstrated elevated serum levels of IL-6 in endometrial cancer patients and showed this was associated with a more aggressive and chemotherapy-resistant endometrial cancer (45). Preclinical data suggest that IL-8 and IL-6 increase resistance to chemotherapeutic treatments in ovarian cancer cells (46,47). Collectively, these observations provide rationale for targeting these chemokines therapeutically in gynecological cancers. Preliminary findings using an anti-IL-6 receptor antibody against ovarian cancer are encouraging (43).

Autotaxin (ATX) is a glycoprotein shown to have a critical role in invasive and angiogenic tumor and endothelial cell behavior (48,49). *ENPP2*, encoding ATX, has been identified as a drug resistance candidate gene (50,52). ATX is multifunctional inducing cell motility, angiogenesis, invasion, and metastasis in multiple models through its cleavage of lysophosphatidylcholine to yield lysophosphatidic acid (LPA), a major gynecologic cancer growth factor. Elevated expression of ATX or aberrant expression of LPA and its receptors has been found in most gynecologic cancers (48). High circulating plasma ATX concentrations

are found in patients with recurrent ovarian cancer (51). Lack of specificity and sensitivity of circulating ATX concentration has precluded its application as a cancer biomarker. However, because of its important role in the development and progression of cancer, numerous studies are attempting to define an ATX inhibitor for clinical testing.

LPA, first described as ovarian cancer ascitic factor, is a growth-promoting lipid isolated from ovarian cancer patient ascites. It induces invasion and metastasis in a wide variety of cancers, including gynecologic cancers (53,56). LPA signals predominantly through G protein-coupled LPA receptors with crosstalk through inflammatory cytokine receptors and receptor tyrosine kinases. These events subsequently activate transcription factors, via the phosphatidylinositol 3-kinase pathway to propagate messages of invasion, angiogenesis, and metastasis (57,58). Wang found that the expression of LPA receptors was significantly increased in ovarian cancer tissues, compared to benign tumors and normal ovarian tissue (59,60). LPA concentrations are elevated in the plasma and/or ascites of ovarian, cervical, and endometrial cancer patients (61); however, the complexity of the relationship between the different LPAs, defined by their lipid substituents, has limited its biomarker development (57).

LPA signaling is central in the progression of most cancers (Fig. 4.3) (53,54,57,62,64). The LPA-Rho-associated kinase pathways have been involved in the course of various cancers,

FIGURE 4.3. Molecular pathways. LPA is a well-recognized and potent prosurvival and angiogenic factor produced and secreted by ovarian cancer. LPA signals through the LPA receptor; a 7-pass transmembrane G-protein coupled receptor. LPA promotes expression of VEGF for angiogenesis and cell survival through the PI3K/AKT, NFκB, and MAPK signaling pathways. Receptor tyrosine kinases, RTK, are a broad family of receptors for multiple growth factors. Their activation also promotes cell survival, invasion, angiogenesis, and proliferation through the ras, PI3K/AKT, NFκB, and MAPK pathways. ERK: extracellular regulated kinase; MAPK: mitogen-activated protein kinase; MEK: MAP-ERK kinase; mTOR: mammalian target of rapamycin; NFκB: nuclear factor κB; Rho-GEF and RHO A are Rho family GTPases.

and inhibiting them decreases cancer invasiveness (58). Rho GTPase family members Rho, Rac, and CDC42 have roles in membrane trafficking, cell adhesion, and remodeling of the actin cytoskeleton in gynecologic and other cancers (32). Inhibition of Rho kinase significantly inhibited LPA-induced invasion and motility in human ovarian and cervical cancer cells in a dose-dependent manner *in vitro* and in xenograft models (58,65). Activation of these Rho kinase pathways lead to actin polymerization, followed by formation of membrane protrusions that are required for migration (32). Similar studies are under way for endometrial and cervical cancer (61).

ADHESION

The concept of shedding and spreading in ovarian and other gynecologic cancers underscores the need for cells to attach to secondary sites and initiate secondary tumor masses. The most common sites of such adhesion is the mesothelial lining of the peritoneum, bowel serosa, or vessel walls (63,64). This occurs via adhesion molecules, of which there are four categories: integrins, cadherins, immunoglobulin super family adhesion molecules (CAMs), and selectins. Each class has different structure, functions, and binding partners, and is expressed in various degrees on the surface of different cells (Fig. 4.4). They participate in cell–cell and/or cell–substratum binding, yielding a complexity of adherence and signaling possibilities. When expression or function of adhesion molecules becomes altered

by tumor progression, new signals are propagated that can promote tumor growth, survival, and metastasis (14,66).

Cell–Cell Interactions

Cadherins are calcium-dependent transmembrane glycoproteins that are expressed in the early stages of development of various tissues. There are three primary cadherins: epithelial (E), neural (N), and placental (P) (67). Each, found commonly in desmosomes and cell junctions, activates intra- and intercellular communication (14). The cadherin intracellular portion connects, through α - and/or β -catenin, to actin microfilaments, anchoring cells to one another (2). Additionally, cadherins interact with various cell surface receptors, including receptor tyrosine kinases, such as epidermal growth factor receptor, to propagate intracellular signals resulting in migration, apoptosis, growth control, and differentiation of tumor cells (66).

E-cadherin, a metastasis suppressor molecule, is the most studied member of the cadherin family (68); its downregulation has been associated with transition to a mesenchymal phenotype, increased invasiveness, tumor progression, and poor survival (2,69,70). When E-cadherin expression is decreased, it is countered by upregulation of N- and P-cadherins. This cadherin switch also has been noted during normal development when migration, budding, and other invasive behaviors are necessary, such as during embryogenesis (71). Physiologic cadherin switching occurs when cells have reached their secondary site and the cadherins again switch and cells alter phenotype. This behavior, mimicked in tumor during epithelial–mesenchymal transition

FIGURE 4.4. Invasion. Cancer cells lose their cell-to-cell (cadherin) and cell-to-matrix (integrin) attachment releasing single cells and allowing for cell migration. The release of proteases (MMPs, serine proteases) promotes ECM degradation forming tracks for cancer cells to migrate and invade surrounding tissues. Integrins can initiate pro-survival or pro-apoptotic signals depending on their attachment to the ECM. Metastatic cancer cells have acquired mechanisms to resist anoikis.

albeit without a secondary cadherin switch, leads to release of β -catenin and its translocation to the nucleus (3). β -catenin then activates signaling for proliferation and invasion (72).

E-cadherin downregulation is associated with higher-grade, increased peritoneal seeding, and decreased overall survival in ovarian cancer (73). Sawada et al. demonstrated that when E-cadherin was silenced, it led to an increase adherence to mesothelial cells in an ovarian cancer *in vivo* model (74). E-cadherin expression has been shown to be lower in tumor cells floating in ascites, pleural effusions, and at the metastatic site, than in the primary tumor (2,75). Downregulation of E-cadherin results from upregulation of a series of zinc-finger transcriptional repressors, *Snail*, *Slug*, *ZEB1/2*, *Twist*, and *SIP1*, expression of which is also associated with increased invasive capability of ovarian cancer cells, resistance to chemotherapy, and poor clinical behavior in ovarian cancer (2,3,66,69,70). Therefore, the role of cadherins, particularly sustaining E-cadherin expression, is a critical defense against cancer cell invasion, migration, and adhesion by maintaining tight cell-to-cell connections.

Cell–Matrix Interactions

The ECM is a complex proteinaceous structure surrounding and supporting cells. It is composed of three major classes of biomolecules: proteoglycans, structural proteins such as collagens and elastins, and specialized matrix proteins such as fibronectin and laminins (76). The ECM can serve many functions, including cellular scaffolding support, binding site for growth factors and cofactors, and modulator of intercellular communication (76). ECM remodeling helps determine polarity and growth of tissues and has become a target of interest in cancer treatment. Many adhesion factors such as integrins, selectins, and CD44 interact not only with other cells, but also with the ECM.

Integrins These are transmembrane receptors named for their ability to integrate the microenvironment and cell signaling. They transmit signals bidirectionally, into and out of the cell, incorporating crosstalk with a variety of cell surface receptors and intracellular signaling proteins (66,77). Integrins are composed of eight α and eighteen β chains combining into 24 heterodimers each of which interacts with a specific repertoire of ligands (67). Each subunit contains a large extracellular domain, a single membrane-spanning domain, and a short cytoplasmic tail (78). Common integrin ligands include the major structural ECM molecules, thrombospondin, fibrinogen, and von Willebrand factor, among others (79). Cell-surface ligands for integrins include members of the immunoglobulin CAM superfamily, such as intercellular adhesion molecule-1 (ICAM-1) (79).

The tripeptide sequence, Asp–Gly–Arg (RGD), is the important ligand recognition site for integrins (80). Binding, whether through RGD or other recognition sites, causes integrin clustering or capping, β -subunit phosphorylation, and association of the cytoplasmic tail with cytoskeletal structures. The actin cytoskeleton is connected to the cytoplasmic integrin tail through the ERM proteins, ezrin, radixin, and moesin (81). Ligand binding also initiates intracellular signaling cascades that provide the machinery needed for cell motility and invasion, and to support survival (3,66,82). Although widely distributed throughout the body, integrins appear to be expressed in low and tightly organized quantities in normal tissue, and up- and downregulated in tumors, including in gynecologic cancers (82). The $\alpha 4 \beta 1$, found commonly on mesothelial and endothelial cells, has been associated with increased peritoneal metastasis, and $\alpha \nu \beta 3$, the vitronectin receptor, is both a driver of tumor proliferation and angiogenesis, via crosstalk with the VEGF receptor, in ovarian cancer (83,84). Integrins $\alpha \nu \beta 3$ and $\alpha \nu \beta 6$ have been associated with decreased patient survival in cervical cancer (85,86).

RGD and integrin binding has been used to focus drug and immunotherapy delivery in preclinical models (87,88). Hood et al. took advantage of integrin-facilitated drug delivery using $\alpha \nu \beta 3$ -targeted nanoparticles to deliver a mutant RAF1 gene into tumor vasculature (89). Xiao found that an integrin-targeting peptide, OA02, enhanced the efficiency of the uptake of nanoparticles into ovarian cancer cells (90). Paclitaxel was added to these nanoparticles and enhanced cytotoxicity was observed. This experiment was validated in ovarian tumor-bearing mice, where paclitaxel-loaded OA02-nanoparticles reduced tumor burden with lower systemic toxicity. Additional experiments have shown that integrin-linked doxorubicin-loaded nanoparticles delivered to tumor vasculature caused inhibition of metastasis and eliminated toxicity normally associated with systemic administration (62,77). Combining vascular targeting antagonists with chemotherapy also is hypothesized to cause more direct penetration of the drug into the tumor, while reducing systemic adverse events (77,78). This treatment concept is awaiting clinical validation for gynecologic cancers.

Selectins This class of molecules contains an epidermal growth factor-like motif and binds glycoproteins and glycolipids bearing sialyl Lewis X (sLe^x) in a calcium-dependent manner (80,91). They initiate the recruitment of lymphocytes by tethering and rolling these cells along the endothelium and are expressed predominantly on leukocytes, platelets, and endothelial cells (91). There are three types of selectins (66). Endothelial (E)-selectin, is triggered by cytokines such as TNF α and interleukin-1, and has a role in leukocyte adhesion at sites of inflammation and/or injury. Platelet (P) selectin is stored in endothelial cells and platelet granules and is activated by histamine and/or thrombin during inflammation. Lastly, leukocyte (L)-selectin is constitutively expressed on leukocytes and acts as a homing receptor for these cells to enter secondary lymphoid tissues. Elevated E-selectin has been associated with various diseases and cancers, including ovarian cancer. E7, an HPV-16 oncoprotein, upregulates the expression of E-selectin in cervical cancers (92). Selectins are thought to interact with tumor cells to shield them while in the circulation to enable subsequent extravasation and migration at the secondary site (66).

CD44, an E- and L-selectin ligand, has been correlated with cancer progression, metastasis, and poor overall survival (66,93). CD44 is the major hyaluronic acid receptor and is expressed by all nucleated cells (63,67). The interaction of CD44 expressed on ovarian cells with hyaluronic acid on mesothelial cells is thought to play a role in tumor dissemination and survival in ovarian cancer (3,55,94). Knockdown of CD44 led to a decrease in adhesion and invasion of ovarian cancer cells (63,94). It has been shown to upregulate proteases involved in breakdown of the ECM, a behavior required for invasion (95). Strobel et al. found that an antibody to CD44 inhibited peritoneal implants of ovarian cancer cells in a mouse model (96). Splice variants of CD44 have the ability to connect to the cytoskeleton, activate Src and Rho GTPase signal pathways, bind chemokines and growth factors, and to act as a coreceptor for other adhesion molecules (3,67).

Therefore, migration of cancer cells into or from blood to tissue requires coordinated sequential interactions of tumor cells with numerous adhesion molecules. The loss of E-cadherin leads to the loss of cell–cell junctions releasing single cells and facilitating migration away from the primary tumor and intravasation (97). Next, selectins facilitate tumor cell adhesion to vascular cells allowing them to transmigrate between the endothelium, followed by basement membrane dissolution and migration into the secondary site. Integrin-associated adhesion to basement membrane and ECM is involved in tumor cell exit from the primary tumor, entry into and exit from the vasculature, and attachment and growth at sites of metastasis. Although the basic concept of targeting these elements in therapy has been studied in animal models, translation to human disease has proved difficult to date.

INVASION/PROTEOLYSIS

The initial steps of invasion include activating signal pathways that regulate cell–cell junction breakdown, tumor or other cell-mediated ECM proteolysis, and migration away from the primary site. Local dissolution of the epithelial or endothelial basement membrane and/or ECM is the key event required for successful invasion. After migration from the primary and successful transit, tumor cells activate mechanisms that permit attachment to endothelial cells or endothelial cell basement membrane or local ECM at secondary sites. Success of this multistep process of invasion leads to successful metastasis.

Proteases are crucial for the degradation of the ECM, which places the tumor cells in direct contact with other cells and creates spaces or tracts through which tumor cells can migrate. Both tumor cells and local cells, such as endothelial cells, stromal, and inflammatory cells, can be the source of activated proteases (98). Proteolysis also unmasks ligands to which receptors of endothelial cells interact, such as integrin RGD moieties (20). The breakdown of the ECM also creates protein fragments, some of which promote and some that inhibit adhesion and migration functions; release of ECM-bound growth factors can also occur. Proteases that are secreted or attached to the cell surface can activate other proteases and cell surface receptors, multiplying the invasion stimulus and allowing adaptive changes in the microenvironment (3).

Matrix Metalloproteinases

Matrix metalloproteinases (MMPs) are a family of metalloenzymes that require cleavage for activation. There are 5 categories: interstitial collagenases, gelatinases, stromelysins, membrane-type, and elastases (99,100). Each of these subclasses has selective substrate specificity with elements of the basement membrane and ECM constituting major substrates. MMPs are secreted by a variety of cancers with MMP-2, -7, and -9 described as active in the gynecological cancer microenvironment (101). The source of the MMP in the microenvironment remains a controversy, with data suggesting that both tumor and microenvironmental elements are involved in a cooperative fashion.

Greater quantity of activated MMP2 was observed by immunohistochemistry staining and immunoblots in ovarian cancer than in normal ovarian tissue (102). MMP2 expression was noted to be higher in stromal cells of invasive cervical cancer compared to CIN3. The increased expression was also correlated with increased stage and worse prognosis (103). A MMP7 polymorphism (MMP7-181G/G) has been demonstrated to be a potential risk factor for developing both endometrial and cervical cancers. It also is associated with an increased risk of higher grade and stage tumors and lymphatic metastasis (102,104,105). Overexpression of MMP7 has been shown in a variety of ovarian cancer cell lines and surgical specimens. Additionally, high levels of MMP9 have been found in ovarian xenograft models (106,107). Elevation of MMPs is not specific to malignant tumors. Other benign tumors and conditions and normal remodeling behaviors may have increased quantities of MMPs (108). This may be one of the reasons that targeting MMPs was previously found to be unsuccessful due to inadequate doses and unexpected adverse events (109,110). Therefore, the importance of this class of enzymes is recognized, although the therapeutic usefulness of targeting these elements is questionable.

Serine Proteases

Serine proteases are ubiquitous, in a variety of tissues, both constitutively and by induction. They have roles in wound

healing and immune response, as well as promoting tumor growth, invasion, and metastasis (111). Plasminogen is an inactive proenzyme that is converted to the active enzyme plasmin, a key protease. Among the many functions of plasmin other than clotting is its requirement for propeptide cleavage and activation of MMPs (99). The plasminogen/plasmin system, in concert with the MMPs, helps regulate the tightly controlled process of ECM degradation. Additionally, this system plays a role in thrombolysis, embryogenesis, cell invasion, and angiogenesis (100).

Hepsin is a type II transmembrane serine protease initially shown to be overexpressed in prostate, renal, and ovarian cancers. Its message is upregulated in 90% of prostate cancers and appears to be exclusively expressed by tumor cells (112). More recently, Matsuo et al. found hepsin to have the strongest expression in endometrial cancer, compared with normal tissue and endometrial hyperplasia. They determined that strong hepsin expression was associated with decreased progression-free and overall survival, although not functioning as an independent prognostic factor (111). Ovarian tumors may also overexpress hepsin (113,114). Xuan et al. showed that antihepsin antibodies significantly inhibited invasion of ovarian cancer cell lines (115). Hepsin may be underappreciated in gynecologic cancer biology.

Serine Protease Inhibitors

There is a large complex family of serine protease inhibitors, the SERPINS (116), some of which are upregulated and functional in gynecologic cancer progression (117,118). One such serine protease inhibitor, secretory leukocyte protease inhibitor (SLPI), a whey acidic protein with anti-inflammatory properties, is overexpressed in breast and epithelial ovarian cancers. Paradoxically, SLPI has been shown to have a progrowth and proinvasion role in ovarian cancer, in part through activation of MMP9, and to be associated with a more aggressive tumor phenotype (119,120). More recently, high levels of SLPI were shown to cause paclitaxel resistance in ovarian cancer cell lines (121). These data have credentialed this serine protease inhibitor as a potential molecular target in ovarian cancer.

The serine protease inhibitor maspin, SERPINB5, has been found to have an antiproliferative and antiangiogenic role in breast, lung, and prostate cancers. Its overexpression in ovarian cancer is associated with promotion of invasion and metastasis (122). Localization of maspin is the deciding factor leading to these opposing roles in cancer. Further studies are needed to clarify this issue.

Protease function constitutes a common requirement in any tissue remodeling process, ranging from embryogenesis to cancer. Hence, it was recognized early on that the metastatic potential of cancer cells relies on the ability to invade and degrade basement membranes (123). Cancer cells benefit from proteolysis to manage their attachment to and detachment from the ECM in addition to providing the overall structure of their invasion and interaction with the microenvironment. The ability to regulate matrix proteolysis and invasion is regarded to be essential in the treatment of cancer.

ANGIOGENESIS AND LYMPHANGIOGENESIS

Angiogenesis

Angiogenesis, the development of new blood vessels, has a key role in cancer progression and development of metastases. Its role in tumorigenesis was first described in 1971 by Folkman. He described that a tumor mass larger than 0.125 mm² exceeds its capacity to acquire nutrients by simple diffusion, and that

further expansion of the tumor would require new blood vessel formation (124–126). Not only do these new vessels provide growing tumors with the necessary nutrients, but they also serve as a route for metastatic dissemination (1). Angiogenesis is regulated by a balance of proangiogenic and angiostatic factors that result from the interaction between tumor cells, endothelial cells, and the microenvironment (127). Inhibitors of angiogenesis can help create a dynamic balance in the tumor milieu, from an angiogenic to a quiescent state, favoring the former one when hypoxia and other stresses are present.

Microvessel density is a method used to quantify vessels in cancer, yielding results that correlate with disease relapse and/or survival in cervical cancer (128), ovarian cancer (129–131), and endometrial cancer (132). The microvessel density significantly and independently correlated with progression free survival and overall survival in endometrial cancer (133). The antibody used to stain the microvessels can also give further information as to the quality of the vessels; CD105, staining endoglin, recognizes more immature vessels and CD31, anti-platelet/endothelial (PE)-CAM, recognizing microvessels (134).

New vessels develop in two ways, by sprouting or splitting. During sprouting, endothelial cells are activated by multiple growth factors and proteases are released, remodeling the surrounding ECM (Fig. 4.5) (135). This allows migration of activated endothelial cells through the matrix. Endothelial cell cords are formed, followed by polarization and formation of the lumen in the immature vessels (136,137). The next step, occurring in normal tissues, is the recruitment of pericytes, vascular smooth muscle cells that surround the vessel outside of the basement membrane. They assist in the secretion of matrix molecules and work with the endothelium to create the basement membrane that stabilizes and further matures the neovessels (138). Pericytes are described as either abnormal or absent in tumor vasculature. This is coupled with demonstration that

the basement membrane has defects in its structure leading to immature and leaky vessels (139,140). Splitting is a different method of vessel development in which the lumen of a preexisting vessel is split to form two new vessels from the original one (141). New microvessels keep the tumor cells within a distance of 100 to 200 μm from the blood supply, permitting successful nutrient absorption by diffusion (142).

Some studies suggest that other mechanisms are involved in tumor angiogenesis. One example of this is the recruitment of endothelial progenitors of different lineages that differentiate into endothelial cells in the right milieu. Vascular leukocytes have been described as a subset of cells marked by both CD45, a leukocyte marker, and vasculo-endothelial (VE)-cadherin. These have been demonstrated in ovarian tumors. Their angiogenic ability has been demonstrated both *in vitro* and *in vivo* (143). Vascular leukocytes are a potential target for antiangiogenic therapy (144).

Vascular Endothelial Growth Factor

Vascular endothelial growth factor (VEGF), first described as vascular permeability factor in 1983 by Dvorak and colleagues, was isolated from rodent ascites after injection of hepatocellular carcinoma cells and later as key factor in blood vessel development as well as permeability (136,145,146). The VEGF family is comprised of seven glycoproteins (VEGF A–E) and placental growth factor-1 and -2, secreted by tumor cells, endothelial cells, stromal cells, leukocytes, and platelets. VEGF-A, the best characterized, has four in-frame isoforms determined by RNA splicing (147). There are three transmembrane receptor tyrosine kinases, the VEGF receptors (VEGFR 1–3). VEGF-A, -B and -E stimulate angiogenesis via VEGFR1 (VEGF-A and -B) or VEGFR2 (VEGF-A and -E). VEGFR are predominantly found in endothelial cells and bone marrow–derived cells, though can

FIGURE 4.5. Angiogenesis sprouting. **A.** Endothelial cells are activated by multiple angiogenic factors secreted by tumor cells and cells of the tumor microenvironment. **B, C.** Proteases are released with the resulting remodeling of the extracellular matrix. **D.** Activated endothelial cells migrate into the stroma forming endothelial cords in the sprouting process. **E.** After cellular polarization, negatively charged glycoproteins and the cytoskeleton retract, forming a vascular lumen. Pericytes are recruited for maturation of the blood vessel, mainly through the action of PDGF.

be found expressed on other cells, including ovarian cancer cells (148). Activation of VEGFR1 and -2 is important for the recruitment, stimulation, and proliferation of endothelial cells, resulting in angiogenesis. Activation of VEGFR2 by VEGF-A has a major permeability-enhancing effect important in the formation of ascites (128,149). VEGF-C and -D activate VEGFR3 and stimulate lymphangiogenesis.

Upregulation of VEGFs is mediated by tissue hypoxia, hypoglycemia, and growth factors. The tumor microenvironment is hypoxic and acidic, both of which stimulate angiogenesis by induction of the hypoxia-inducible factor 1 α (HIF-1 α) (10,150). VEGF and VEGFR-1 are under the transcriptional regulation by HIF-1 α (151). HIF-1 α is overexpressed in several solid tumors, including ovarian carcinomas (152). Tumor growth factor signaling cascades, such as the LPA, NF- κ B, and phosphatidylinositol-3' kinase (PI3K) pathways, are activated by tumor and stromal-induced growth factors and can result in VEGF induction in ovarian cancer (153–156).

Ovarian carcinomas that have high expression of VEGF were found to result in shorter patient survival (157); concordant results were found with serum concentrations of VEGF suggesting poor patient prognosis (158). VEGF is secreted into malignant ascites by ovarian cancer cells, contributing to the increasing ascites burden through its effects on vascular permeability (159–161).

Platelet-Derived Growth Factor

Platelet-derived growth factor (PDGF) stimulates angiogenesis and also activates stromal and tumor cells (162–165). Its expression has been demonstrated in epithelial ovarian carcinomas but not in borderline ovarian tumors (166). PDGF is a dimeric protein composed of two closely related A- and B-chain polypeptides encoded by independent genes (167). Three heterodimers are formed that act in an autocrine and paracrine fashion in ovarian cancer and angiogenesis through two receptors, PDGFR β and α (166). PDGF-BB stimulates migration of endothelial cells by increasing transcription and secretion of VEGF by PDGFR β -expressing endothelial cells; activation of PI3K is important for this response (163,168). PDGF-mediated secretion of VEGF protected endothelial cells *in vitro* from apoptosis caused by serum starvation, indicating an indirect role of PDGF in supporting tumor angiogenesis through activation of survival pathways (168). The presence and potential prognostic value of the PDGFs and PDGFRs in ovarian cancer has not translated to clinical value as most of the multikinase inhibitors tested to date, such as imatinib, with inhibition of PDGFR activity have shown limited activity in gynecologic cancers (166,169–172).

Fibroblast Growth Factor

The fibroblast growth factor (FGF) family includes several ligands interacting with four FGF receptors (FGFR). Gene amplification of FGFR2 has been found in ovarian and endometrial cancer (173). FGFs are involved in proliferation, migration, and differentiation of vascular endothelial cells in a VEGF-independent manner; they also are secreted by and/or effect a wide variety of other cell types in the tumor microenvironment. FGF-1 and -2 are potent direct and indirect angiogenic factors. They also stimulate the secretion of other angiogenic factors including angiopoietin 2 and VEGF (174,175). FGF-2 also interacts with PDGF-BB, stimulating angiogenesis and attraction of vascular smooth muscle to stabilize newly formed vessels (176). FGFR1-IIIc responds to VEGF and is implicated in resistance to anti-VEGFR therapy. The combination of anti-VEGFR and anti-FGFR therapy has been examined in mouse models and was successful after failure of single agent anti-VEGFR treatment (156,177). FGF has been found in high concentrations in ascites of ovarian cancer patients (178). It remains to be determined

whether multitargeted agents will offer greater clinical benefit than specific VEGF pathway inhibitors (179).

Lymphangiogenesis

The lymphatic system is composed of the lymphatic vessels and lymphoid tissue. It has three primary physiologic functions: (a) maintenance of the blood volume through reabsorption of interstitial fluid; (b) immunological surveillance; and (c) transport of fat from the bowel to the liver. The first two functions are involved in cancer progression and metastasis (180). There are three main elements in lymphangiogenesis, VEGF-C, VEGF-D, and their receptor, VEGFR3 (180). These VEGFs also are induced by hypoxia and angiogenic signals, tumor cells, infiltrating inflammatory cells, and stromal cells. Lymph vessels are low-pressure vessels with limited basement membrane and no stromal components, permissive to entry and exit of tumor cells, immune cells, and pathogens and therefore are a ready route for metastasis (181–183). High expression of VEGF-D in epithelial ovarian tumor was associated with higher FIGO stage, intratumoral lymphatic vessels, tumor lymphatic invasion, and lymph node metastasis. VEGF-D, intratumoral lymphatics, and lymphatic invasion are independent prognostic factors for overall survival and disease-free survival in patients with epithelial ovarian carcinoma (184).

METASTASIS

Metastasis, the spread of malignant cells from the primary tumor to other sites, is the culmination of the steps discussed above—gain and loss of cell and matrix adhesion, proteolysis, and migration—and requires cancer cells to overcome many barriers for successful travel and secondary growth. Cancer cells utilize physiologic mechanisms that maintain cellular and tissue homeostasis, to promote tissue invasion, cell survival and proliferation. Survival in alternative microenvironments requires that successful metastasis also use mechanisms to overcome loss of critical stimuli, such as matrix attachment and nutritional restriction (2,3,185).

Anoikis

Anoikis, derived from Greek and meaning homelessness (5,186), is a specific apoptotic process triggered by loss of, or inappropriate cell attachment to the ECM. It is a physiologic phenomenon that maintains cell and tissue homeostasis. Resistance to anoikis is important to cancer cells because it allows them to resist apoptosis during the metastatic process, such as upon single cell release from a primary tumor and migration within the matrix or when floating in effusions (11,187). Cell–cell adhesion prevents anoikis, even in the setting of ECM detachment (188). Ovarian cancer cells shed into the peritoneal fluid form viable clusters, resist anoikis, and later can adhere and invade into serosal mesothelium (189).

The mechanism by which anoikis is triggered relies on the loss of interaction between integrins and the ECM. This causes loss of prosurvival signaling through Akt/PI3K and the raf-ERK pathway (Fig. 4.4) (4,190). Suspended cells and attached cells have very different cytoskeletal structures suggesting that the cytoskeleton also regulates survival signaling in anoikis. The disruption of structural elements or changes in cell shape might trigger anoikis (191) making the cytoskeleton a therapeutic target.

Cancer cells resist anoikis by constitutive activation of survival pathways or inhibitors of apoptosis. In ovarian cancer TrkB, a neurotrophic tyrosine kinase receptor is a potent suppressor of

caspase-associated anoikis that is found to be overexpressed in ovarian cancer (192). TrkB was found overexpressed in high-grade ovarian carcinomas and multicellular spheroids from ascites. OVCAR-3 cell spheroids also overexpressed TrkB compared to monolayer cultures. Overexpression of TrkB was associated to activation of the PI3K-AKT survival pathway in cells that survived anoikis (192). Another mechanism of anoikis resistance is attributed to the deletion or mutation of the tumor and metastasis suppressor, phosphatase and tensin homolog, PTEN. PTEN is prevalent in both endometrioid endometrial and ovarian cancers and negatively regulates AKT signaling pathway by dephosphorylation of phosphatidylinositol-4,5-bisphosphate (193). PTEN mutation removes inhibition of the AKT survival pathway activation and thus promotes anoikis resistance.

Autophagy and Cancer

Autophagy is a physiologic process that occurs in normal cells, but is induced in many types of cancer, including gynecologic cancers. Activation of autophagy can lead to cell survival or cell death depending upon the context and the stimuli, and therefore is likely exploitable for cancer therapy (11). Autophagy is tightly controlled lysosomal auto-digestion activated to maintain cellular homeostasis during the dynamic balance between cell survival and cell death. It participates in invasion, angiogenesis, and metastasis through its role in protein recycling and genome protection (9). When nutrients are deficient due to poor vascularity, intracellular molecules are recycled through autophagy to sustain viability (194,195). Hypoxia induces intracellular reactive oxygen species (ROS) that can injure intracellular proteins and upregulate autophagy (196). ROS are removed by autophagy, protecting the DNA from damage (9).

BIOMARKERS

Biomarkers are important tools to guide treatment and patient care. It is important to differentiate predictive from prognostic markers since they have different application in the management

of patients. Predictive biomarkers function to differentiate outcome to intervention, such as therapy or radiation, whereas prognostic biomarkers are independent of treatment (197). Prognostic biomarkers differentiate overall outcome, such as progression-free and overall survival within a population and have little bearing on individual patients. Despite good response rates to front line treatment of gynecological cancers, relapse rates can be very high in advanced ovarian cancer (198). Predictive and prognostic markers would help to optimize the use of existing therapies and the use of biological targeted therapies and improve quality of life by predicting high risk for toxicities.

Many elements of invasion, angiogenesis, and metastasis have also been examined for predictive, and more commonly, prognostic value. Application of new technologies including the high-throughput extensive genomic, genetic, and proteomic tools are uncovering a plethora of findings that will need to be examined in the context of diagnostics, predictive, and prognostic value and for their relationship to angiogenic, invasive, and metastatic behavior in gynecologic malignancies.

Clinical Application: Therapy Directed Against Invasion, Angiogenesis, and Metastasis

Questions that remain in the clinical arena include the following: (a) the value of specific rather than promiscuous inhibitors; (b) whether therapeutic antibodies that cause antibody-directed cellular cytotoxicity are more active than simple neutralizing antibodies; (c) what the best strategy is for combination development, with other targeted agents and/or chemotherapy; and (d) whether therapy is best in treatment and/or in maintenance of response. In order to have confidence in these targeted inhibitors of angiogenesis, invasion, and tumor dissemination, validation and illustration of the mechanism is key, with demonstration that the activated target is present, affected by the therapeutic, and that modulation of the target by the therapeutic is correlated with outcome (197,199). Many studies have been done with this increasing collection of new agents, some with promise of future benefit (Fig. 4.6).

FIGURE 4.6. Angiogenic agents in ovarian cancer. Results of phase I-III trials of antiangiogenic agents alone and in combinations are plotted. Response rate and frequency of 6-month progression-free survival are shown.

Molecular-Targeted Agents: Monoclonal Antibodies

Antiangiogenic antibodies. *Bevacizumab* is a recombinant humanized version of the murine antihuman VEGF monoclonal antibody. This VEGF-neutralizing antibody inhibits VEGF-induced signaling, resulting in reduced angiogenesis and tumor growth. It has been U.S. FDA-approved for renal cell, lung, and colon cancers. In metastatic colon cancer, it prolonged survival when given in combination with chemotherapy; activity has been shown in breast, ovarian, endometrial, and cervical cancers (200–205). One of the first observations of activity of bevacizumab was reduction in gynecologic cancer ascites burden (206–208). Single-agent bevacizumab (GOG 170D) demonstrated a 21% response rate, with 40% surviving progression free at least 6 months (209). Progression-free survival at 6-month rate was 23.9% and 40.4% in cervical (GOG 227C) and endometrial cancer (GOG 229E), respectively (202,205).

The addition of bevacizumab to front-line chemotherapy and to maintenance therapy in epithelial ovarian cancer was evaluated in two pivotal phase III trials, GOG 218 and ICON 7. GOG 218 was a three-arm, placebo-controlled trial of front-line paclitaxel and carboplatin to which either concurrent bevacizumab or concurrent and maintenance bevacizumab were added. A progression-free benefit was seen in women who received both concurrent and maintenance bevacizumab at 15 mg/kg (14.1 vs. 10.3 months; HR, 0.717; $p < 0.0001$) (179). No significant difference in overall survival has been demonstrated (39.7 vs. 39.3 months; $p = 0.45$). ICON 7, a randomized phase III trial, evaluated first-line paclitaxel/carboplatin alone or in combination with bevacizumab followed by bevacizumab maintenance using 7.5 mg/kg (210). Progression-free survival was enhanced in the bevacizumab arm (HR, 0.81; 95% CI, 0.70–0.94; $p = 0.0041$), and interim analysis has revealed no significant improvement in overall survival. A post-hoc exploratory subgroup analysis found a survival improvement for patients with stage IV or stage IIIC disease with >1 cm residual tumor (HR, 0.64; 95% CI, 0.48–0.85; $p = 0.002$).

The addition of bevacizumab to second-line chemotherapy was evaluated in platinum-sensitive recurrent ovarian cancer. The phase III OCEANS trial was a two-arm, placebo-controlled study of gemcitabine and carboplatin, with experimental arms of concurrent and maintenance bevacizumab until disease progression. Patients who received concurrent and maintenance bevacizumab had a longer progression-free survival (12.4 vs. 8.4 months; HR, 0.484; 95% CI, 0.388–0.605; $p < 0.0001$) (211). Again, there was no difference in overall survival. The results of GOG 218, ICON 7, and OCEANS have raised significant questions regarding patient selection, dose, duration, and timing of therapy.

There are several randomized trials evaluating bevacizumab and chemotherapy in recurrent (GOG 213 and AURELIA) and newly diagnosed (GOG 241, 252, and 262) ovarian cancer, cervical cancer (GOG 240), and endometrial cancer (86P). Bevacizumab is also being evaluated in combination with a variety of agents including mTOR, PARP, VEGFR, and SRC inhibitors, as well as with vascular disrupting agents.

Anti-EGFR family antibodies. *Cetuximab* is a recombinant chimeric antibody to EGFR that is presently approved for treatment of metastatic colon cancer and unresectable head and neck cancer, with activity in breast and non-small cell lung cancer. However, cetuximab has minimal activity as a single agent and lacks significant activity in combination with chemotherapy or radiation in patients with recurrent ovarian (GOG 146P) or cervical cancer (GOG 227E, 76DD) (212–215). The high incidence of gastrointestinal and metabolic toxicity has precluded further development. Similar minimal activity of other methods

of inhibition of EGFR has been seen. Currently, there is no role for EGFR interruption in gynecologic malignancies.

Trastuzumab is a monoclonal antibody against EGFR-2 (Her2) that prolongs survival in Her2-positive breast cancer in both the adjuvant and metastatic settings (216,217). The only role for trastuzumab in gynecologic cancers to date appears to be in combination with chemotherapy and/or other HER2/EGFR inhibitors in uterine papillary serous cancers (218). Rare cases of true mucinous ovarian cancer have been found expressing very high Her2 and responding to trastuzumab. This observation is being followed.

Molecular Targeted Agents: Kinase Inhibitors

Antiangiogenic Agents. A number of small-molecule inhibitors of the VEGF receptors and other angiogenic pathways have been developed and reached clinical trials. VEGFR2 is most commonly targeted with preclinical data showing this approach to be active in reducing endothelial cell proliferation, migration, and vascular development, and xenograft models have confirmed activity in a number of solid tumors (219).

Selective VEGFR Inhibitors. *Cediranib* is an oral tyrosine kinase inhibitor (TKI) that targets all three VEGFRs and c-kit. Two phase II single-agent studies in recurrent EOC have been conducted. Partial response frequency ranged from 13% to 17%, with hypertension and fatigue being the most common grade 3 adverse events (220). Cediranib is being evaluated in combination with carboplatin and paclitaxel in a phase III trial (ICON6) in women with recurrent disease (221).

Mixed Kinase Inhibitors, Including VEGFRs. *Sorafenib* is an oral Raf-kinase and VEGFR-2 inhibitor that has been approved for treatment of metastatic renal cell and hepatocellular cancers (222,223). Single-agent sorafenib in women with recurrent ovarian cancer resulted in partial response in 2 patients, 20 with stabilization, and 6-month progression-free survival was 24% (GOG 170F) (224). A randomized phase II study comparing maintenance sorafenib 400 mg twice daily to placebo in advanced ovarian or primary peritoneal cancer in complete remission following surgery and one previous chemotherapy regimen has been reported as negative (IGCS, 2012). A phase I trial of *sorafenib* and *bevacizumab* in combination yielded a response rate of 47% in heavily pretreated ovarian cancer patients (197,225); evaluation of tumor biopsies, cytokine concentrations, and vascular imaging confirm an antiangiogenic signaling effect of the combination. A phase II trial of bevacizumab combined with sorafenib is presently accruing at the National Cancer Institute.

Nintedanib (BIBF1120) inhibits VEGFRs 1, 2, and 3, PDGFR- α and - β , and FGFRs 1, 2, and 3. A phase 2 placebo-controlled nintedanib maintenance trial in patients who responded to previous (at least second-line) chemotherapy reported a 36-week progression-free survival of 16.3% versus 5.0% with placebo ($p = 0.06$) (226). The most common significant adverse effects in the nintedanib arm included elevated transaminases and diarrhea. A phase III randomized placebo-controlled trial of nintedanib in combination with carboplatin and paclitaxel followed by maintenance nintedanib or placebo (AGO-OVAR12/LUME-Ovar1) in first-line treatment of EOC has completed enrollment.

Pazopanib is a TKI that targets all three VEGFRs, both PDGFRs, and c-kit. The phase II trial of pazopanib in ovarian cancer patients with initial complete CA125 response yielded a CA-125 response rate of 31%, where 29% of patients with measurable disease had stabilization (227). A phase III randomized placebo-controlled maintenance trial of pazopanib 800 mg daily (AGO-OVAR16) has completed enrollment and is maturing. Pazopanib has also been evaluated in cervical cancer (228) with improved progression-free survival (HR, 0.66; 90% CI, 0.48–0.91;

$p = 0.013$) and overall survival (HR, 0.67; 90% CI, 0.46–0.99; $p = 0.045$) compared to lapatinib, an EGFR/Her2 TKI. There was no benefit of combination lapatinib and pazopanib.

Sunitinib, an inhibitor of VEGFRs and PDGFRs (229,230), resulted in a response rate of 16.7% in a noncontinuous arm and 5.4% with continuous dosing in a phase II trial in platinum-refractory EOC (AGO-OVAR-2.11) (231). Sunitinib has minimal activity as a single agent in cervical cancer (232). The GOG has activated a phase 2 trial to evaluate sunitinib in patients with recurrent clear cell ovarian cancer (GOG254). Other VEGFR inhibitors that also target the PDGFRs and/or c-kit include vatalanib and axitinib. All are under investigation in ovarian cancers and some in other gynecologic malignancies.

Cabozantinib is an oral TKI that inhibits c-Met, ALK, and VEGFR2, and has been shown to reduce tumor growth and angiogenesis (233). Simultaneous targeting of the MET and VEGF signaling pathways may be a promising strategy to improve anti-tumor activity by blocking alternative stimulatory pathways. Reported in abstract only, a phase II randomized discontinuation trial of XL184/cabozantinib showed an overall clinical benefit defined as partial response and stable disease of 58%. The most common significant adverse effects were hand-foot syndrome (10%), diarrhea (8%) and fatigue (4%). The agent continues to be evaluated in women with refractory ovarian cancer.

Vandetanib, a dual VEGFR and EGFR inhibitor, was examined in lung and ovarian cancers because of the recognized presence and activity of both targets. A phase II study with tissue acquisition was negative (234). However, examination of signaling pathways, cytokine concentrations, and functional vascular imaging demonstrated that only EGFR was successfully inhibited at tolerable oral doses. VEGFR2 was not inhibited, nor were there changes in circulating VEGF, hypertension, or contrast changes in MRI. Vandetanib is currently being evaluated in a randomized phase II trial in combination with docetaxel in patients with recurrent ovarian cancer.

Alternative Antiangiogenesis Therapies. *Aflibercept* (VEGF-trap) is a unique fusion protein that acts as a high-affinity soluble VEGFR decoy, inhibiting VEGF-mediated events (235). Unlike bevacizumab, aflibercept has the ability to bind to other VEGF family members, including placental growth factor. A multicenter phase II study of aflibercept in recurrent ovarian cancer yielded objective response rates of 7.3% and 3.8% with 4 mg/kg and 2 mg/kg doses, respectively. The study did not achieve its primary endpoint; however, results from a phase 1 or 2 trial of aflibercept in combination with docetaxel in patients with recurrent ovarian cancer reported substantial antitumor activity (236). Aflibercept is also being evaluated in patients with endometrial cancer.

AMG 386 is a peptide-Fc fusion protein that inhibits angiogenesis by binding angiopoietin-1 and -2 and blocking interaction with the Tie2 receptor. A phase II trial of weekly paclitaxel with AMG 386 or placebo for patients with recurrent ovarian, fallopian tube, or primary peritoneal carcinoma was conducted. The median progression-free survival with paclitaxel plus placebo and 3 or 10 mg/kg of AMG386, respectively, was 4.6, 5.7 (HR vs. placebo, 0.75; 95% CI, 0.56–1.00; $p = 0.21$), and 7.2 months (HR vs. placebo, 0.76; 95% CI, 0.57–1.02; $p = 0.23$) (237). The side-effect profile was acceptable. Continued studies are ongoing to further evaluate the activity of AMG 386 in women with recurrent and newly diagnosed ovarian cancer and endometrial cancer.

COMBINATION THERAPY

Further refinement of targeted therapy is focused on the hypothesis that inhibiting biologic targets in combination may be more

effective than alone. Both targeted agents with cytotoxics and multitargeted agent studies have been initiated. To date, these approaches have not borne out promise in the phase III trials that have been completed. This underscores the importance of biological material acquisition for proof of mechanism to understand the successes and more importantly the failures of such studies. These results challenge the use of this strategy in an unselected patient population and indicate the need to develop clinical nomograms or predictive biomarkers to direct anticancer therapies. Adverse events have also limited targeting some elements of angiogenesis, invasion, and metastasis.

Drug Schedules

It has long been recognized that some drugs may have altered mechanisms of action or better pharmacokinetics when the drug schedule is modified. Paclitaxel and docetaxel have been shown to have antiangiogenic activity *in vitro* and *in vivo* (238,239). The concentrations used in those preclinical studies were at or lower than the concentration range used in the clinic; cisplatin, the control, was shown to have little effect on angiogenesis. Several chemotherapeutic agents have been shown to have antiangiogenic activity when administered in small doses in a continuous exposure approach (240). A phase II trial revealed activity of bevacizumab in combination with low-dose oral cyclophosphamide in recurrent ovarian cancer with a response rate of 24%, median progression-free survival of 7.2 months, and median overall survival 16.9 months (241); it is unknown if this is superior to single-agent low-dose daily cyclophosphamide. Weekly scheduling of topotecan, paclitaxel, or docetaxel combined with bevacizumab also have been reported to have activity in patients with ovarian cancer (242,243). Whether the effects are due to modulation of angiogenesis, invasion, and metastasis rather than using the cytotoxic effect another way is yet to be demonstrated.

CONCLUSIONS

Continued scientific, epidemiologic, and clinical advances are critically needed until successful, reproducible, and accurate early detection of gynecologic tumors becomes routine. Understanding the biology, regulation, and implications of the process of invasion and angiogenesis will continue to drive new biomarker and therapeutic target identification and intervention. The similarity between dysregulated invasion and angiogenesis and unregulated motility of metastasis allows the potential for a dual-purpose intervention. The tumor's interaction with its microenvironment becomes the focus for scientific dissection and therapeutic application (1). Here, the process of autocrine and paracrine regulation, signal pathway activation, and cell-cell conversation are critical. The use of the newer and high-throughput technologies to identify collections of biologic targets rather than one gene or protein at a time can make the process more streamlined and provide a broader view of the interaction of events. In addition, it is clear that there are numerous convergent and divergent angiogenic processes. New targets are emerging that may overcome angiogenesis escape, including novel endothelial cell and pericyte targets. Several small molecules including vascular disrupting agents, DLL4-NOTCH pathway inhibitors, and endoglin (CD105) are in clinical trials or presently under development. Together, improved understanding, study of events in the patient populations, and cooperative and collaborative progress will allow us to overcome invasion and metastasis, the major causes of morbidity and mortality associated with gynecologic cancers.

Development and Identification of Tumor Serum Markers

ALEKSANDRA GENTRY-MAHARAJ ■ IAN JACOBS ■ USHA MENON

Tumor markers are defined as molecules or substances produced by malignant tumors that enter the circulation in detectable amounts. They indicate the likely presence of cancer or provide information about its behavior. In management of cancer, the most useful biochemical markers are the macromolecular tumor antigens, including enzymes, hormones, receptors, growth factors, biologic response modifiers, and glycoconjugates. A substantial number of substances have been investigated as potential tumor markers over the past decade and the list is continually growing owing to new technology employed in biomarker discovery.

Tumor markers can be used for risk stratification, screening, differential diagnosis, prognosis, predicting, and monitoring response to therapy and detecting recurrence (Table 5.1). The performance of a tumor marker depends on its sensitivity (percentage of patients with cancer correctly identified as a result of a positive test), specificity (percentage of the population without cancer correctly identified as a result of a negative test),

and positive predictive value (PPV, percentage of patients with positive test that have the cancer, true positives) (Table 5.2). An ideal tumor marker should have a 100% sensitivity, specificity, and PPV. However, in practice such a marker does not exist. As the majority of markers are tumor-associated rather than tumor-specific, and are elevated in multiple cancers, benign and physiologic conditions, they lack specificity. In addition, if sensitivity is low, a normal result may not exclude malignancy. Tumor markers discovered thus far contribute to differential diagnosis but are not themselves diagnostic. This restricts their use, with few exceptions, to monitoring therapeutic response and follow-up. Tumor markers currently used in nongynecologic malignancies include:

1. Carcinoembryonic Antigen (CEA), the most commonly elevated marker in colorectal cancer, whose preoperative assessment is recommended by the American Society of Clinical Oncology (ASCO) as it may complement surgical staging and help in choosing the most appropriate surgical treatment. Abnormal preoperative levels may also indicate higher risk of recurrence but there is no concrete evidence as to whether patients with colorectal cancer would benefit from adjuvant therapy based on preoperative CEA alone (1). CEA is, however, not used in screening or early diagnosis.
2. CA-15-3, measurements of which have been advocated (ASCO) in monitoring response to treatment in breast cancer when the disease is not measurable.
3. Prostate-specific antigen (PSA) is used in screening for prostate cancer but its use as a stand-alone marker is not recommended. Most guidelines recommend a PSA test followed by digital rectal examination with definitive diagnosis always requiring a biopsy. PSA may have a role in detecting disease recurrence and monitoring treatment in patients with prostate cancer (2).

Table 5.1 Tumor Markers and Their Potential Uses**1. Risk stratification**

Adjusting risk categorization for an individual without the disease. The marker could then be used in screening or prevention if these are proven to be effective

2. Screening

Screening to detect cancer earlier than it would have been using clinical signs and symptoms

3. Differential diagnosis

Use of serum and tissue tumor markers to establish the tissue of origin of a newly diagnosed cancer by differentiating between the cancer and benign conditions

4. Prognosis

Markers used to determine prognosis in a patient, i.e., risk of invasion and metastasis in the absence of therapy

5. Prediction

Ability of a marker to determine the likelihood of sensitivity or resistance to specific therapy

6. Monitoring

Monitoring patients either during or after therapy to determine the status of the cancer. Patients are usually monitored during primary therapy but also during therapy for metastatic disease to determine if the patient is responding to the treatment or if an alternative therapy is needed

Table 5.2 Parameters of Tumor Marker Assays

Tumor Marker Result	True Tumor Status	
	Positive	Negative
Positive	A (True positives)	B (False positives)
Negative	C (False negatives)	D (True negatives)

Sensitivity = True positives / All with tumor = $A / A + C$

Specificity = True negatives / All tumor free = $D / D + B$

Positive predictive value (PPV) = True positives / All with positive tumor-marker result = $A / A + B$

This chapter focuses on those markers that are clinically relevant to female genital tract malignancies.

OVARIAN AND FALLOPIAN TUBE CANCERS

Women have approximately a 1% to 2% lifetime risk of developing ovarian cancer (OC) and it accounts for 4% of cancers diagnosed in women, with over 225,000 new cases diagnosed worldwide each year (3). Incidence rates are highest in the U.S. and Northern Europe and lowest in Africa and Asia. It is associated with the highest mortality rates of all female genital tract malignancies. Around 85% of cases occur over the age of 50, and 80% to 85% of cancers are epithelial in origin. Epithelial ovarian cancer (EOC) may be serous, mucinous, endometrioid, clear cell, transitional, and undifferentiated. The most common histologic subtype of EOC is serous OC, which usually presents at advanced stages and has the poorest outcomes (4). However, in the reproductive age group germ cell tumors, granulosa cell/sex-cord tumors, mucinous, and endometrioid tumors are more common. Only a few tumor markers have been validated for clinical use with the best known among them being cancer antigen 125 (CA-125).

CA-125

CA-125 was first described by Bast et al. in 1981. It is a 200-kDa glycoprotein recognized by the OC-125 murine monoclonal antibody (5). CA-125 carries two major antigenic domains: domain A (binds monoclonal antibody OC-125) and domain B (binds monoclonal antibody M11) (6). The current second-generation heterologous CA-125-II assay incorporates M11 and OC125 antibodies, while the original homologous assay was with OC125 alone. Currently there are a number of CA-125 assays that correlate well with each other (7,8).

CA-125 is expressed by amniotic and coelomic epithelium during fetal development. It is widely distributed in adult tissues (mesothelial cells of the pleura, pericardium and peritoneum, tubal, endometrial and endocervical epithelium) but is not expressed by the surface epithelium of normal fetal and adult ovaries with the exception of inclusion cysts, areas of metaplasia, and papillary excrescences (9). It therefore lacks complete specificity for OC.

The level of CA-125 in body fluids or ovarian cysts does not correlate well with serum levels. This is probably due to the serum concentration being reflective not only of the production of the antigen by the tumor but other factors that affect its release into the circulation. The widely adopted cut-off at 35 kU/L routinely used in clinical practice is based upon the distribution of values in 99% of 888 healthy men and women (10). However, levels of CA-125 tend to be lower in postmenopausal women or in patients who have undergone hysterectomy; levels of 20 U/mL and 26 U/mL have been suggested (11–13). Approximately 85% of patients with epithelial ovarian cancer have CA-125 levels of greater than 35 U/mL (10,14). Raised serum levels are found in 50% Stage I and greater than 90% Stage II–IV cancer (15) (Table 5.3). CA-125 levels are more frequently elevated in serous compared to mucinous, clear cell, and borderline tumors (15–17). CA-125 can be elevated in other malignancies (pancreas, breast, colon, and lung cancer) (Table 5.4) and in benign conditions (Table 5.3) and in physiologic states such as pregnancy, endometriosis, and menstruation (15). Diagnostic accuracy of raised CA-125 in postmenopausal women is improved by absence of many of these nonmalignant conditions (Table 5.3).

Table 5.3 CA-125 Elevations in Benign Disorders and Ovarian Cancer

		Cut-off
Healthy women	Premenopausal ^a	35 kU/L
	Postmenopausal ^b	20 kU/L
Disease	Condition	CA-125 elevations over 35 kU/L (%)
Benign ovarian disease	Overall (all benign tumours) ^c	29%
	Ovarian cysts ^c	14%
	Germ cell tumours (mature teratoma) ^c	21%
	Sex cord stromal tumours (thecoma, fibrothecoma) ^c	52%
	Cystadenoma, adenofibroma, cystadenofibroma ^c	20%
	Serous epithelial tumours ^c	20%
	Mucinous epithelial tumours ^c	18%
	Benign, NOS ^c	27%
	Benign, other (normal ovaries) ^c	22%
Benign disorders of the female genital tract	Abscess/hydrosalpinx/POD ^c	37%
	Fibroid (leiomyomas) ^c	26%
	Acute salpingitis ^d	40.4%
	Chronic salpingitis ^d	8.3%
	Pelvic inflammatory disease ^e	29.4%
	Endometriosis/endometrioma ^c	67%
	Endometriosis (Stage I) ^d	8.0%
	Endometriosis (Stage II) ^d	19.6%
	Endometriosis (Stage I/II combined) ^d	11.5%
	Endometriosis (Stage III) ^d	44.7%
	Endometriosis (Stage IV) ^d	86.7%
	Endometriosis (Stage III/IV combined) ^d	50.4%
	Endometriosis (overall) ^d	24.3%
Other disorders ^d	Cirrhosis ^d	67.1%

Screening

Screening is the identification of unrecognized disease in apparently asymptomatic population by use of tests, examinations, or other procedures that allow earlier diagnosis of the disease than if it had presented clinically. The main goal of cancer screening is to reduce mortality from the disease by either preventing it (if a premalignant condition exists) or diagnosing it earlier when treatment is more effective. Just detection of the cancer of interest before it is symptomatic cannot justify screening.

There are cancer-specific criteria detailing which cancers could most benefit from screening which build on the WHO criteria for all diseases (Table 5.5) (18). To be effective and applicable to the population at large, screening needs to achieve high sensitivity/specificity, PPV, and negative predictive value (NPV) (Table 5.6), and be acceptable to the populations to be tested. The PPV depends on the prevalence of the disease within the population, with more false positives detected if disease prevalence is low. Well-organized national screening programs, such as for cervical screening, are required to realize the true potential of screening in reducing disease-specific mortality.

In a national screening program, issues that have to be considered include frequency of screening, age of the population to be screened, well-defined mechanisms for referral and treatment of screen-detected abnormalities, comprehensive information systems that not only send invitations at predefined intervals but also recall those with abnormalities for assessment and schedule follow-up of those treated, and quality assurance protocols to monitor and evaluate the efficacy of the screening program. Furthermore, for a screening strategy to be successful, uptake and compliance with screening has to be high.

Table 5.4 CA-125 Elevations in Nonovarian Malignancies

Cancer	CA-125 elevations over 35 k U/L (%)
Nongynecologic malignancies	
Breast ^a	17.6%
Colorectal ^a	15.1%
Pancreas ^a	52.6%
Lung ^a	29.5%
Gastric ^a	30.9%
Biliary tract ^a	45.8%

The first cancer screening program to be implemented was for cervical cancer in 1940. However, its impact on mortality has only been evident since the introduction of organized screening programs. Breast cancer screening began in the 1960s

Table 5.5 World Health Organization Criteria for a Screening Program

1. The condition sought should be an important health problem
2. There should be accepted treatment for patients with recognized disease
3. Facilities for diagnosis and treatment should be available
4. There should be a recognizable latent or early symptomatic stage
5. There should be a suitable test or examination
6. The test should be acceptable to the population
7. The natural history of the condition, including development from latent to declared disease, should be adequately understood
8. There should be an agreed policy on whom to treat as patients
9. The cost of case finding (including diagnosis and treatment of patients diagnosed) should be economically balanced in relation to possible expenditure on medical care as a whole
10. Case finding should be a continuing process and not a “once and for all” project

Table 5.6 Parameters Crucial when Evaluating Screening Tests**1. Test validity**

Accuracy/Validity of the screening test is evaluated by sensitivity and specificity of the screening test. Sensitivity is the correct identification of the individuals with disease out of all with positive screening results, whereas specificity is the proportion of people with negative screening test who do not have the disease

2. Measuring test performance

Easier to measure in research setting than in a screening program. The proportion of the population with detectable preclinical disease is an important factor judging the effectiveness of a screening strategy. An ideal test would detect the disease early; those that can only detect advanced disease indicate a long screening interval or poor sensitivity of the test

3. Positive Predictive Value (PPV)

Proportion of individuals with a positive screening test that will have the disease. A PPV of 10% means that only one out of ten individuals investigated had the disease, the other nine were investigated unnecessarily

4. Negative Predictive Value (NPV)

Proportion of individuals with a negative test result who are correctly diagnosed as not having the disease. In clinical setting, high NPV means that the test only rarely misclassifies a sick person as being healthy

5. Test sensitivity versus program sensitivity

Test sensitivity (screening test applied once) can be different from program sensitivity (screening test applied multiple times to the same population). Program sensitivity is higher in cases where population adherence to screening is high, because if the cancer was missed in the first round of screening, it is very likely it would be picked up on the second round. However, if adherence with screening is poor, there will be cancers that will be missed and diagnosed only when symptomatic

6. Validity

RCTs are the gold standard for evaluating effectiveness of a screening strategy but need a large number of participants and take a long time to complete (at least 15 years). Case-control studies have been used to evaluate screening tests but suffer due to potential selection bias

7. Lead time bias

Screening advances the time of diagnosis, therefore the duration of time between when a cancer is detected by screening and when it would have been detected due to symptoms is referred to as lead-time. However, if there is no effect on survival, i.e., the cancer is diagnosed through screening, but the individual dies at the same time as if detected by symptoms, it would falsely appear that the survival is longer in the screened population when it is not. This is called lead-time bias

8. Length-bias sampling

Screening tends to pick up less aggressive, slow-growing cancers and less likely to pick up more aggressive, faster-growing cancers. Length-time bias refers to the greater likelihood of screen-detected cancers to be slow-growing—this would give the false impression of improved survival of screen detected cancers

9. Overdiagnosis

Screening can result in overdiagnosis, detection of the cancer that would not have been detected during that person's lifetime if it were not for screening. These lesions are not easy to distinguish from those that become clinically significant. There may be serious consequences for these patients. However, overdiagnosis probably contributes a small percentage of harm compared to the benefits of screening

10. Selection bias

Individuals who participate in screening programs are usually more health conscious, healthier, more aware of signs and symptoms of the disease, have better access to treatment, and are more likely to adhere to treatment. Hence, they might have better outcomes if they develop cancer than the unscreened population. Selection bias is higher in clinical trials than in screening programmes that are associated with high uptake

when mammography became available. The initial study of 62,000 women aged between 40 to 64 years lasted over 25 years and provided the first experimental evidence of the efficacy of the breast cancer screening strategy (19). In the 1970s, lung cancer screening trials using chest radiograph and sputum cytology were initiated, followed by the first colorectal cancer screening trial in 1975. Trials of prostate and ovarian cancer screening started in the 1990s (20).

Screening can also contribute to primary prevention, as in colorectal cancer screening, where removal of adenomas substantially reduces the incidence of colorectal cancer. However, there are downsides to screening too. Breast cancer screening has had a lot of criticism in recent years as it picks up less aggressive forms of the disease, ductal carcinoma *in situ* (DCIS) that would have otherwise gone unnoticed during an individual's lifetime. Compliance with colorectal cancer screening is an issue probably due to the nature of the test. Prostate screening has been hampered by low sensitivity of the PSA test when used alone.

Screening for ovarian cancer continues to be investigated in the research setting with CA-125 the only tumor marker currently being explored in large trials. When it is interpreted using a cut-off, 2.9% of healthy postmenopausal women will have elevated CA-125 levels, limiting its use as a stand-alone test (21). In the multimodal screening strategy, this is overcome by use of transvaginal ultrasound (TVS) as a second-line test in women with elevated CA-125 levels so that high specificity (99.9%) and four or less operations for each OC detected can be achieved (22,23). Ovarian morphology has been used to refine algorithms for interpreting TVS in postmenopausal women with elevated CA-125 (24,25). Over the last decade, CA-125 interpretation in the context of screening has been further improved by a more sophisticated approach incorporating age, menopausal status, and the rate of change of CA-125 values over time (26–28). This statistical algorithm (Risk of Ovarian Cancer, ROC), based on the age-specific risk of the disease and the behavior of CA-125 with time in women with ovarian cancer versus normal controls, has improved both the sensitivity and specificity of CA-125

interpretation (28). Prospective evaluation of the ROC algorithm in a randomized controlled trial (RCT) of 13,582 postmenopausal women aged over 50 demonstrated high specificity (99.8%; 95% CI, 99.7–99.9) and PPV (19%; 95% CI, 4.1–45.6) for primary invasive EOC (26). Algorithms, such as the ROC, rely on modeling the behavior of a biomarker from disease onset to clinical presentation and use data that may take years to accumulate.

Four large trials on OC screening (OCS) have reported in the past decade. The Kentucky Screening Study (29), a single-arm annual ultrasound screening study of 25,327 women, reported a sensitivity for primary epithelial ovarian cancer of 81% with 9.3 operations carried out per case detected. For primary invasive OC, sensitivity decreased to 76.3%. Encouragingly, the majority of the primary ovarian cancers (82%) were early stage (I/II). Recently, the study reported that at a mean follow-up of 5.8 years, the women in the trial (primary invasive OCs, screen positives and interval cancers) had a longer 5-year survival ($74.8\% \pm 6.6\%$) compared to the women from the same institution treated by the same surgical and chemotherapeutic protocols that were not screened ($53.7\% \pm 2.3\%$) ($p < 0.001$). Moreover, 70% of the screen-detected OCs were at early stage (I/II) (30), but this was not a RCT and there may be a range of factors responsible for the apparent impact of screening.

The Japanese Shizuoka Cohort Study of Ovarian Cancer Screening (31) was an RCT of 82,487 low-risk postmenopausal women who were screened using an annual ultrasound and CA-125 using a cut-off. Sensitivity of 77.1% and specificity of 99.9% was reported for this trial with OC detection rates of 0.31 per 1000 women at prevalent screen and 0.38–0.74 per 1000 women at subsequent screens. Proportion of stage I OC was higher in the screened group (63%) than in the control group (38%) but did not reach statistical significance (31). The effect on mortality has not yet been reported.

The U.S. Prostate, Lung, Colorectal and Ovarian (PLCO) Cancer Screening Trial enrolled 78,237 women aged 55 to 74 years, with 34,202 women randomized to OCS. Women were screened using serum CA-125, using a cut-off of 35 kU/L, and transvaginal ultrasonography for 3 years followed by CA-125 alone for a further 2 years. Evaluation and management of positive screening tests was at the discretion of participants' clinicians. Women were followed up for a median of 12.4 years (25th to 75th centile, 10.9–13.0) (32). During the prevalence screen in 28,816 women, 29 ovarian, tubal, and peritoneal cancers were detected, of which 20 were invasive, and nine were borderline. A total of 4.7% women had an abnormal scan and 1.4% an abnormal CA-125. The PPV for invasive cancer was 3.7% for abnormal CA-125, 1% for abnormal transvaginal scanning and 23.5% if both tests were abnormal (33). The results of the first 4 rounds of screening in 34,261 postmenopausal women reported 89 invasive ovarian/peritoneal cancers, of which 60 were screen detected. Only 28% of screen-detected cases were stage I/II. The overall ratio of surgeries per screen-detected cancers was 19.5:1, having decreased over the years from 34% in the first year of screening to 15% to 20% in subsequent years (34).

In The UK Collaborative Trial of Ovarian Cancer Screening (UKCTOCS), 202,638 postmenopausal women aged between 50 and 74 years were randomized to either control or annual screening with ultrasound or a multimodal strategy in a 2:1:1 fashion (35,36) (www.ukctocs.org.uk) (Fig. 5.1). In the multimodal group, CA-125 is interpreted using the ROC algorithm (that takes into account the absolute value of CA-125 and serial levels over time) to triage the women into low, intermediate, and elevated risk. Those at intermediate risk have a repeat CA-125 in 12 weeks, whereas those with elevated risk are referred for a transvaginal scan and repeat CA-125 in 6 weeks. In addition to assessing the effect of ovarian cancer on mortality, the trial will also address acceptability, compliance, costs, performance characteristics of the 2 screening strategies, and the physical and psychological morbidity of screening. The prevalence screen suggests that multimodal strategy has superior sensitivity (89.4%) and specificity (99.8%) to ultrasound screening alone (sensitivity 84.9%; specificity 98.2%) for primary ovarian cancer.

For primary invasive ovarian cancers, the sensitivity of multimodal screening remained at 89%, whereas that of the ultrasound-based strategy decreased to 75.0% (36). Results are expected in 2015.

Currently, there is lack of evidence whether screen-detected cancers include a significantly high proportion of high-grade serous carcinomas in early stage or only those subtypes that confer better prognosis.

Although it has been shown that screening can detect ovarian cancer early (31) and provide a survival benefit in the screened group, only two randomized trials have so far reported on the impact of OCS on survival or mortality. The first one, involving 22,000 women carried out in the 1980s, which used sequential CA-125 and Transvaginal scanning (TVS), reported improved survival of 72.9 months in the screened versus 41.8 months in the control group (22). Recently, the PLCO trial (32) reported no mortality benefit with OCS with 118 and 100 deaths in the screening and control arm, respectively (mortality rate ratio of 1.18 (95% CI, 0.91–1.54) (Fig. 5.2). These data did not demonstrate a mortality benefit from simultaneous screening with CA-125 (using an absolute cut-off) and TVS scanning. Moreover, excess morbidity of carrying out surgery in women with false-positive results was 5.1% (32). However, the mortality data from PLCO needs to be interpreted with caution as concerns have been raised about the trial design, as 40.6% of women were diagnosed after screening ended, CA-125 was interpreted using an absolute cut-off (rather than a time series algorithm), and management of screen positives was at the discretion of the treating clinician (rather than via a well-defined protocol) (37). UKCTOCS, the largest OCS trial (38), will report in 2015, and should address some of these issues. On the basis of current evidence, women from the general population should only be screened in the context of research trials.

Women who have a strong family history of ovarian cancer constitute only 5% to 10% of women with ovarian cancer. These women (from families with multiple first-degree relatives affected by breast and ovarian cancer, or Lynch syndrome) have a greater than 10% lifetime risk of developing ovarian cancer, and are considered to be high-risk. Most of this risk is attributable to mutations in the *BRCA1*, *BRCA2*, and *MMR* genes with cumulative risks by the age of 70 years for ovarian cancer of 40% (35% to 46%) in *BRCA1*-mutation carriers, 18% (13% to 23%) in *BRCA2* mutation carriers (39), and 10% to 12% in women with mutations in the *MMR* genes (40). These women often seek screening, but the current recommendation is that they should consider risk-reducing bilateral salpingo-oophorectomy once they have completed their families.

There are a number of studies evaluating OC screening in the familial context (41,42). There is some evidence that a strategy based on annual screening is not effective in detecting early stage disease in this population. An approach based on 3 to 4 monthly screening is currently being evaluated in the UK Familial Ovarian Cancer Screening Study (UKFOCSS, prospective screening study based on annual TVS and CA-125 interpreted using the ROC algorithm, with over 5700 women) (43) and trials are under way under the auspices of the Cancer Genetics Network and Gynecological Oncology Group (44). Both trials are using the ROC algorithm with a screening interval of 3 to 4 months. One of the trials in the high-risk group has reported so far; the U.S.-based Cancer Genetics Network (CGN) (45) used the ROC algorithm to screen 2,343 high-risk women at 3 monthly intervals. Thirty-eight women underwent surgery following 6,284 screens; 5 ovarian cancers were detected, of which 2 were prevalent (1 early, 1 late stage) and 3 were incident (all early) cases resulting in a PPV of 13%. Three further occult cancers were detected at risk-reducing salpingo-oophorectomy and 1 woman developed an interval (late stage) cancer (46). The results of the UK trial are anticipated in 2013.

There are some recent developments with immediate implications for OC screening. These include novel insights into tumor biology, as reflected in the proposed classification of OCs into

FIGURE 5.1. The United Kingdom Collaborative Trial of Ovarian Cancer Screening (UKCTOCS). Women in the trial, based on the risk of ovarian cancer (ROC) value, are stratified into **low risk** (ROC: $<1 / 3,500$), and returned to annual screening with the next blood test in one year; **intermediate risk** ($<1 / 1,000$ and $<1 / 3,500$) with a repeat CA-125 in 12 weeks; and **elevated risk** ($>1 / 1,000$) with Level II screen (CA-125 and TVS) scheduled in 6-8 weeks, with earlier screens arranged where there was a high index of suspicion. Those with persistent abnormalities on Level II screen are referred to a gynecologic oncologist. The screening protocol has been described in detail elsewhere. Roc, risk of ovarian cancer; TVS, transvaginal ultrasound.

FIGURE 5.2. Prostate Lung Colorectal and Ovarian (PLCO) Cancer Screening Trial. Women in the trial underwent 4 annual screens with CA-125 (interpreted using a cut-off of 35 kU/L) and TVS and 2 further screens with CA-125 alone. If an abnormality was detected on screening, the women underwent referral to their physician. Final outcome (OC mortality) was reported in 2011. TVS, transvaginal ultrasound.

Type I, slow growing cancers with good prognosis such as low-grade serous, low-grade endometrioid, clear cell, mucinous, and transitional (Brenner) carcinomas, and more aggressive Type II, which include high-grade serous, high-grade endometrioid, undifferentiated tumors and carcinosarcomas (47). Screening strategies including biomarker discovery and refining of ultrasound indices need to take into account both types with a focus on detection of type II cancers, which account for over 80% of OC mortality. To date, the goal of screening was limited to detection of early-stage disease (48,49) but the work of Crum et al. supports a model of “fimbrial-ovarian” serous neoplasia, with a proportion of serous OCs starting as premalignant serous tubal intraepithelial cancer (STIC) lesions in the distal fallopian tube and spreading to the ovary (50). This raises the possibility of primary prevention in the future.

In a 1980s biobank study, CA-125 was found to be raised in 59 out of 236 (25%) stored serum samples collected from women with ovarian cancer 5 years before diagnosis (13). Data from a Japanese OCS study indicate that, in serous-type ovarian cancer, first elevation of CA-125 to diagnosis has a shorter interval compared with those with nonserous-type disease (1.4 vs. 3.8 years; $p = 0.011$). Although 47% of nonserous-type ovarian cancers developed from slightly elevated CA-125 levels between 35 and 65 kU/L, 75% of serous ovarian cancers developed suddenly from a normal CA-125 level (<35 kU/L) (51). A model of natural history of OC developed by Brown and Palmer suggests that on average, it takes over 4 years for *in situ*, stage I or stage II cancers to become clinically apparent, and approximately 1 year for stage III/IV cancers (52). Serous cancers are less than 1 cm in diameter during the occult period. The model suggests that for a screening strategy to be able to detect 50% of the cancers before they progress to stage III, an annual screen would have to detect tumors 1.3 cm in diameter (53). Unpublished data from UKCTOCS suggest that detecting such small high-grade serous cancers may be feasible using the ROC algorithm.

Recently, using samples from 112 OC patients and 706 controls from PLCO, Urban et al. demonstrated that Human Epididymis protein 4 (HE4) had higher sensitivity of confirming Type II cancers (40% vs 20%) than Type I cancers (18.8% vs 56.2%) compared to TVS. HE4 had higher sensitivity (35.7%) than TVS (28.6%) as a first-line test. The sensitivity of HE4 was improved by using TVS as a second-line test. Combination of HE4 and CA-125 (32.1%) had a better sensitivity than TVS alone (20.2%). However, the authors stress that diagnosing HE4-associated tumors is not necessarily better than diagnosing TVS-associated tumors in terms of outcome (54).

Whether a raised CA-125 in asymptomatic postmenopausal women is a predictor of nongynecologic cancer is not yet clear. Data from the RCT of 22,000 postmenopausal women (22) reported that elevated serum CA-125 was not a predictor of a nongynecologic malignancy on mean follow-up of 2,269 days (55). However, it was associated with significantly increased risk of death from all causes in the next 5 years (56). In contrast, data from the Norwegian OCS trial of 5,500 women showed that breast and lung cancer were overrepresented among women with elevated CA-125 (57). Both trials indicate that elevated CA-125 is a risk factor for death from malignant disease. These data indicate that steps should be taken to rule out other malignancies such as breast, lung, and pancreas in asymptomatic postmenopausal women with rising CA-125 levels with no evidence of gynecologic malignancy.

One of the limitations of CA-125 is that 15% to 20% of ovarian cancers do not express the antigen. This may partly be caused by CA-125 forming circulating immune antibodies containing complexes bound to the free antigen (58). Rosen et al. (59) explored 10 potential serum markers that could complement CA-125 in 65 ovarian cancers with weak or absent CA-125 tissue expression. All specimen lacking CA-125 expressed human kallikrein 10 (HK10), human kallikrein 6 (HK6), osteopontin, and claudin 3. A small proportion of CA-125 negative ovarian cancers expressed DF3 (95%),

vascular endothelial growth factor (VEGF) (81%), MUC1 (62%), mesothelin (MES) (34%), HE4 (32%), and CA-19-9 (29%). MES and HE4 showed the greatest specificity when reactivity with normal tissues was considered. Differential expression was also found for HK10, osteopontin, DF3, and MUC1 (59). Several of these markers are currently being assessed in nested case control studies using serum samples from ovarian cancer screening trials.

The screening trials in the general population have focused on postmenopausal women as around 90% of ovarian cancers are sporadic and occur in women from the general population over the age of 50. A number of risk factors affect ovarian cancer risk in the general population, such as oral contraceptive use, parity, and hysterectomy, which can be used to determine an individual's risk. Recent efforts have focused on identification of low- and moderate-penetrance genes that predispose women to ovarian cancer (60–63). It is therefore very likely that population-screening strategies in the future will use a risk-stratification tool that combines these factors.

Additional Markers

In the past few years, major efforts have been made to identify either a better marker or a panel of markers that would improve the performance of CA-125 in the context of screening. However, most of the studies used clinical samples (rather than preclinical samples), so their findings are more relevant to differential diagnosis of benign from malignant masses, avoiding unnecessary operations in women with benign lesions and ensuring that surgery, where there is high suspicion of ovarian cancer, is undertaken by trained gynecologic oncologists in tertiary-care centers (64–66). Using a CA-125 cut-off of 35 kU/L combined with imaging has been shown to achieve a sensitivity of 94% and specificity of 90% for differential diagnosis of ovarian cancer from benign disease (67). The performance of various other markers to detect ovarian cancer has been evaluated: Interleukin-6 (IL-6), Interleukin-7 (IL-7), soluble Interleukin-2 receptor (sIL-2R), Tumor Necrosis Factor (TNF), Soluble receptors of TNF (sTNF-R), Macrophage Colony-Stimulating Factor (M-CSF), CA-15-3, CA-72-4 or TAG-72, CA-19-9, OVX1, CASA/OSA, Growth factors, Tetranectin, Tumor-Associated Trypsin Inhibitor (TATI), GAT (Galactosyltransferase associated with tumor), LASA (lipid-associated sialic acid), VEGF (vascular endothelial growth factor), IAP (immunosuppressive acid protein), Lyso-phosphatidic Acid (LPA), Prostatin, Cadherin, Shed glycans, Dipeptase 1; however, despite a plethora of studies, none been shown to be useful in clinical practice. Limited sensitivities and specificities constrain their use in screening.

The only promising marker in the last decade has been serum human epididymis protein 4 (HE4). Preclinical samples from asymptomatic women from the PLCO trial were used to assess the performance of 49 ovarian cancer biomarkers using the ProBE design (68) of a prospective-specimen collection, with retrospective-blinded evaluation study design (69). The performance of “standard” tumor markers, such as CA-125, HE4, CA-72.4, and CA-15.3, in prediagnostic samples drawn within 6 months of cancer diagnosis was comparable to that in clinical samples. Performance was poorer for markers such as prolactin, transthyretin, or apolipoprotein A1, which may reflect the individual response to the cancer, in prediagnostic specimens. Serum CA-125 remained the single best biomarker for ovarian cancer, with sensitivity of 86% (95% CI, 0.76–0.97) in cases where blood was drawn within 6 months of diagnosis, with the second best marker being HE4, with sensitivity of 73% (95% CI, 0.60–0.86). For all markers, sensitivity declined in specimens more remote than 6 months from diagnosis. However, the limitation of this study was that CA-125 was used in “real time” for triaging women for diagnostic work up for ovarian cancer (70). A recent study by Anderson et al. (71) using specimens from the

Carotene and Retinol Efficacy Trial showed that a panel including CA-125, HE4, mesothelin may provide signal for ovarian cancer 3 years before diagnosis; this is consistent with data from the UK screening trials.

Another recent study using a nested case-control design in laboratory-blinded samples obtained before cancer diagnosis and matched controls from the (PLCO) Cancer Screening Trial demonstrated that none of the 5 predictive models, each containing 6 to 8 biomarkers, nor a model derived from all of the 28 markers evaluated, showed improvement over CA-125 alone (72). There are 2 possibilities why studies have failed to show improvement over CA-125; either the current technologies are unable to identify biomarkers with greater or complementary potential for screening, or the available technologies, powerful as they are, have not yet been applied appropriately either in discovery or in validation, with one of the main obstacles being use of clinical as opposed to prediagnostic/preclinical samples (69).

A limited number of studies have investigated the utility of proteomic markers in preclinical diagnosis of ovarian cancer. The most recent study of preclinical samples from 118 OC cases and 951 age-matched controls from the PLCO trial collected less than 12 months before cancer diagnosis showed that although CA-125 was elevated in 61.5% of the 65 OC cases that had CA-125 data available, a combination of CA-125 and apolipoprotein A1, truncated transthyretin, transferrin, hepcidin, β_2 microglobulin, connective tissue activating protein III, and interalpha-trypsin inhibitor heavy-chain 4 did not improve sensitivity of using CA-125 alone (73).

To ascertain the optimal biomarker panel to distinguish early-stage OC from healthy women, Yurgovetsky et al. had used multiple xMAP bead-based immunoassays using 96 serum biomarkers and applied it to samples from 139 patients with early-stage ovarian cancer, 149 patients with late-stage ovarian cancer, and 1,102 healthy women. The highest sensitivity (86%) and specificity (98%) was achieved using a 4-marker panel consisting of CA-125, HE4, CEA, and VCAM-1. In an independent blinded validation set (44 patients with early-stage ovarian cancer, 124 patients with late-stage ovarian cancer, and 929 healthy women), sensitivity for early stage (I/II) disease remained at 86% but increased to 95% for late stage disease (III/IV) while maintaining high specificity (98%) (74). This panel justifies evaluation in a screening context.

Although limited progress has been made in identifying new biomarkers, it is likely that novel algorithms that incorporate serial change over time of some of these markers alongside CA-125 may significantly improve screening performance.

Differential Diagnosis of an Adnexal Mass

The factors that influence whether a tumor marker is incorporated into clinical practice are outlined in Table 5.7. Serum CA-125 is of value in differential diagnosis of benign and malignant adnexal masses, especially in postmenopausal women. Using an upper limit of 35 U/mL, sensitivity of 78%, specificity of 95%, and PPV of 82% were achieved for malignant disease in women with palpable adnexal masses (75). This has since been confirmed by numerous studies (76–78). Further improvements in specificity were achieved by using a panel of markers (CA-125 II, CA-72-4, CA-15-3, and LASA) and an artificial neural network approach to differentiate malignant from benign pelvic masses (79).

The Risk of Malignancy Index (RMI) has been the most valuable clinical tool used in the past two decades. It combines serum CA-125 values with ultrasound findings and menopausal status. The initial study demonstrated a sensitivity of 85% and a specificity of 97%. Patients with an elevated RMI score had on average a 42-fold increase in the background risk of ovarian cancer (80).

Table 5.7 Criteria for Incorporating Tumor Marker into Clinical Practice

1. The intended use of the tumor marker must be clearly outlined
 2. The difference between ‘positive’ and ‘negative’ populations must be sufficient to guide change in clinical management
 3. The estimate of difference must be reliable and validated
- Assay must be technically stable, reproducible and accurate
- Clinical study must have been suitably designed and have a sufficient power to address the utility of intended use
- Statistically analysis must be rigorous

Source: Hayes D.F. (2011). Biomarkers. In V.T. DeVita Jr, T.S. Lawrence, S.A. Rosenberg, R.A. DePinho, R.A. Weinberg (Eds), *Cancer: Principles and Practice of Oncology*. (pp. 694–701). Wolters Kluwer Health; Lippincott, Williams & Wilkins.

Since then, the RMI has been validated extensively. A systematic review of 109 eligible studies assessing accuracy of models for predicting malignancy in ovarian masses showed that while all models had acceptable sensitivity and specificity, RMI was the best predictor. Using 200 as the cut-off, the pooled estimate for sensitivity for preoperative assessment of an adnexal mass was 78% for a specificity of 87% (81). Varying the RMI cut-off (25 to 1,000) in combination with specialist ultrasound (US), magnetic resonance imaging (MRI), and radioimmunoscintigraphy (RS) provided a sensitivity of 94% and a specificity of 90%, therefore suggesting this approach rather than using an RMI cut-off value of 250 alone to improve correct referral of cancer patients to a cancer center (67).

RMI over 200 has recently been evaluated in a Danish study of 1,159 women with pelvic mass referred to a tertiary center for further preoperative investigations, showing that using this cut-off, a sensitivity and specificity for ovarian cancer versus benign pelvic mass of 92% and 82%, respectively, and PPV and NPV of 62% and 97% could be achieved therefore indicating that RMI ≥ 200 is a reliable tool in OC diagnosis (82). RMI has also been investigated in an Asian population, in a retrospective study of 209 women undergoing surgery for adnexal mass. Using a cut-off of 200, RMI 1 gave sensitivity of 70.6%, specificity of 83.9%, PPV of 75%, and NPV of 80.6%, while RMI 2 improved sensitivity to 80% with a specificity of 78.2%, PPV of 71.6%, and NPV of 85.1%, thus favoring RMI 2 as the index better suited at predicting malignancy (83). In differential diagnosis of borderline tumors from benign adnexal masses, RMI IV (based on preoperative serum CA-125 and CA-19-9 levels, ultrasound findings and menopausal status) cut-off of 200, the Receiver Operator Characteristic area under the curves for serum CA-125, CA-19-9, ultrasound score, RMI IV(CA-125), and RMI IV(CA-19-9) were 0.580, 0.625, 0.548, 0.694, 0.734, and 0.711, respectively (84).

RMI when combined with subjective ultrasound was shown to be superior to a combination of CA-125 and HE4 and menopausal status (in the risk of ovarian malignancy assay, ROMA), in a single-center prospective cohort study of 432 women with a pelvic mass who were scheduled to have surgery (85).

Despite lower accuracy in borderline, stage I invasive, and nonepithelial ovarian cancers, the RMI is a simple, easily applicable method in the primary evaluation of patients with adnexal masses which identifies ovarian cancers more accurately than any other criterion used in diagnosis of this disease (86).

Prognosis

Preoperative serum CA-125 levels are related to tumor stage, tumor volume, and histologic grade of OC. Although initial studies did not find preoperative CA-125 to be an independent prognostic factor (87–89), it may be of value in localized/early-stage

disease (90). In a study of 118 patients with FIGO stage I epithelial OC, compared to those with stage I and preoperative serum CA-125 levels <65 U/mL, stage I patients with preoperative serum CA-125 ≥ 65 U/mL had a significantly longer survival (91). This finding has been confirmed in a study of 600 patients from gynecologic cancer centers in Australia, USA, and Europe with stage I epithelial ovarian cancer. On multivariate analysis, preoperative serum CA-125 greater than 30 U/mL and age greater than 70 years at diagnosis were the only independent predictors for overall survival (OS). Levels of CA-125 of ≤ 30 U/mL (over histologic cell type, sub-stage and grade) were able to identify a subgroup of FIGO stage I patients with a genuinely good prognosis and survival who could possibly be spared from adjuvant chemotherapy (92). Additional parameters such as cyclooxygenase-2 overexpression in combination with preoperative CA-125 level of under 30 U/mL have been recently found to be independent predictors of survival in univariate and multivariate analyses (93). However, CA-125 does not appear to be an independent prognostic factor in advanced ovarian cancer (90).

Postoperative CA-125 levels have been found to be significant prognostic factors (87). Patients with a low CA-125 prognostic score composed of two CA-125 values, one taken preoperatively and the other taken 1 month after surgery, have significantly better prognosis than patients with high scores (94). In the immediate postoperative period, CA-125 levels can be elevated as a result of the abdominal surgery and irritation of the peritoneal cavity; therefore, measurements are best postponed for at least 4 weeks (95).

During primary chemotherapy, serum CA-125 half-life is an independent prognostic factor in patients with advanced epithelial ovarian cancer, both for complete remission and survival (96–98). The most commonly used cut-off is a CA-125 half-life of 20 days (98–100). In patients with CA-125-positive tumors, other useful prognostic indicators of survival are the serum CA-125 levels prior to third course of chemotherapy (96,101,102) and the slope of the CA-125 exponential regression curve. In patients treated on maintenance chemotherapy and achieving a clinically defined complete response to primary chemotherapy with a baseline CA-125 level of ≤ 35 U/mL, the baseline CA-125 level before initiation of maintenance chemotherapy strongly predicts the risk of subsequent relapse. Patients with pre-maintenance baseline CA-125 values ≤ 10 U/mL have a superior progression free survival compared to those with higher levels even if in the normal CA-125 range (103).

Serum CA-125 continues to be of prognostic significance when ovarian cancer recurs, with patients with normal serum CA-125 levels (≤ 35 U/mL) at relapse having a better prognosis than patients with elevated levels (104).

Apart from CA-125, other markers have been evaluated as those with prognostic value. More recently, soluble MUC1 and serum MUC1-specific antibodies have been shown to be prognostic for poor clinical response and reduced OS in both platinum-resistant as well as platinum-refractory OC treated with interleukin 2 (IL-2) (105). The mean levels of anti-MUC1 IgG was higher in patients with progressive disease, both at early ($p = 0.025$) and late ($p = 0.052$) time points during the IL-2 treatment.

Another marker, survivin, with levels higher in serous OC than in benign epithelial tumors, could not be used for differential diagnosis of OC from benign masses but could be used as a prognostic marker for OC as its levels were positively correlated with age, advanced stage, and poor disease-free survival (106).

Monitoring Response to Treatment

It is now established that serum CA-125 levels reflect progression or regression of disease in over 90% of ovarian cancer patients with elevated preoperative levels (107) (Fig. 5.1). These findings have resulted in the widespread use of serum CA-125 levels to

monitor the clinical course of ovarian cancer and its response to chemotherapy (108). However, CA-125 should not be used as the sole criterion to determine clinical response (109) as studies involving second-look laparotomy have confirmed that CA-125 values of less than 35 U/mL do not exclude active disease (110). The pattern of CA-125 over time is a more useful parameter than using an arbitrary cut-off level (100,101,111,112). Precise mathematical definitions to evaluate response to treatment have been suggested with 50% response corresponding to a 50% decrease in CA-125 after 2 samples, confirmed by a third sample collected at least 28 days later and a 75% response defined as a serial decrease over 3 samples of greater than 75% (113,114). Prechemotherapy CA-125, its half-life, nadir concentration, and time to nadir have a univariate prognostic value for disease-free and OS in a multicenter French study (115).

Detecting Recurrence

Among patients with elevated CA-125 levels at diagnosis, serial monitoring following initial chemotherapy can lead to the early detection of recurrent disease. Median lead-time prior to clinical progression of 63 to 99 days has been demonstrated between marker detection of disease progression and clinically apparent progressive disease (116,117). The value of marker lead-time depends ultimately on a patient's remaining therapeutic options, and the clinical value of this approach is unclear (118).

In a study of 39 patients with elevated serum CA-125 at time of diagnosis and complete clinical and radiographic response to initial treatment with normalization of serum, Santillan et al. reported that a relative increase in CA-125 of 100% (odds ratio [OR] = 23.7; 95% CI, 2.9–192.5) was significantly predictive of recurrence. From baseline CA-125 nadir levels, an absolute increase in CA-125 of 5 U/mL (OR = 8.4; 95% CI, 2.2–32.6) and 10 U/mL (OR = 71.2; 95% CI, 4.8 to >999.9) were also significantly associated with the likelihood of concurrent disease recurrence. These data suggest that for patients in complete clinical remission, a progressive low-level increase in serum CA-125 levels is strongly predictive of disease recurrence (119).

CA-125 measurements together with thin-section computer tomography (CT) and careful review of the clinical history have been recommended in follow-up of patients with ovarian carcinomas (120). However, a study of 58 patients with recurrent ovarian cancer revealed that 98% of recurrences were identified by physical examination and CA-125, with ultrasound and CT not providing additional clinically relevant information during follow-up (121).

In a population-based study of 331 Dutch EOC patients, van Altena et al. showed a significant association of CA-125 nadir ≤ 5 kU/L with both longer PFS and longer OS (log-rank test $p < 0.01$ and $p = 0.03$, respectively). It was also an independent prognostic variable (HR = 1.51; 95% CI, 1.04–2.31) for PFS next to histologic type, FIGO stage, and residual tumor after surgery (122). However, the MRC OVO5/EORTC55955 trial has shown no value in CA-125 monitoring in the follow-up of ovarian cancer patients. The trial included 1,442 patients with normal CA-125 level following platinum-based therapy. Patients whose levels rose to twice the upper limit of normal (529 women) were randomized to immediate (based on CA-125 levels) or delayed chemotherapy (the latter when signs and symptoms of recurrence were present). The women randomized to monitoring started chemotherapy at a median of 4.8 months earlier than those in the delayed arm but this did not result in difference in survival between the arms (early arm: median 25.7 months, 95% CI 23.0–27.9; delayed arm: median 27.1, 95% CI 22.8–30.9; HR: median 0.98, 95% CI 0.80–1.20; $p = 0.85$). Therefore, Rustin suggests that CA-125 should only be measured if there is a suspicion of relapse or at patient's request (123). The pattern of CA-125 throughout a patient's clinical course of the disease is presented in Figure 5.3.

FIGURE 5.3. Correlation between serum CA-125 and clinical course in ovarian cancer.

HE4

Human epididymis protein 4 (HE4) is a glycoprotein in the epithelial cells of the epididymis. In ovarian cancer, increased serum levels and expression of the HE4 WAP four-sulphide core domain 2 (*WFCD2*) gene have been demonstrated (124).

Mean serum HE4 in patients with malignant ovarian lesions (248.7 pM) is much higher than in controls (34.1 pM) or women with benign lesions (39.1 pM) (Table 5.8). HE4 levels are decreased in pregnancy (median levels of 30.5 pmol/L) (125) and levels around 50 and 60 have been demonstrated in pre- and postmenopausal women, respectively (126), which increase with age (median 109.5 pmol/L in women over 80). HE4 levels are lower in many of the benign conditions that usually elevate CA-125 levels (Table 5.9), especially in women with endometriosis.

HE4 can also be elevated in other cancers (Table 5.10). Initial report stated that its specificity is superior to CA-125 (124) and of particular value for early-stage disease (127). Combining CA-125 with HE4 has been found to increase sensitivity while maintaining high specificity (127); but more recently, it has been reported not to be superior to CA-125 in clinical setting (128).

More recently, the superiority of HE4 in differential diagnosis of ovarian cancer as a single marker was reported. Moreover, the diagnostic prediction (AUC 0.864) was improved by Risk of Malignancy (ROMA) index (AUC 0.897) (129). Serum HE4 has

lower sensitivity than CA-125 for early stage disease, but has better sensitivity and specificity in differential diagnosis of benign from malignant pelvic masses, especially in premenopausal patients (124). Although HE4 has recently been shown to improve the performance of CA-125 (129), in a Swedish study of 114 OC, 45 borderline and 215 patients with benign ovarian tumors, Partheen et al. showed that HE4 did not out-perform CA-125 (benign vs. malignant AUC 86.8% for CA-125 and 84.4% for HE4; benign versus Stage I OC 72% for HE4 and 76% for CA-125) (130). Very recently, Schummer et al. demonstrated that in patients who are developing a recurrence, HE4 rises earlier than CA-125 with a lead-time of up to 4.5 months (131). It can also be elevated in patients who do not express CA-125 at sufficient levels to make a clinical decision. MMP7 and Mesothelin are, however, not as useful in predicting recurrence to add to CA-125. However, as HE4 levels fail to normalize at the end of treatment, it is possible that it can be used as a marker predicting poor prognosis.

Recent developments with regard to the HE4 marker include its commercial availability (when combined with CA-125) as a test for preoperative prediction of low/high risk of epithelial OC as well as being approved by the U.S. Food and Drug Administration for monitoring recurrence or progression of epithelial ovarian cancer. For the former, it is included in the Risk of Ovarian Malignancy Algorithm (ROMA), a qualitative serum test that combines the results of HE4 EIA, ARCHITECT CA-125 II and menopausal status into a numerical score. In premenopausal women, ROMA value $\geq 13.1\%$ predicts high risk of epithelial OC; ROMA value $\geq 27.7\%$ is deemed to represent high risk of OC in postmenopausal women (132).

When looking at new biomarkers/combination of markers, it is important to establish the normal range in healthy individuals, especially if the marker has been shown to be very promising, such as HE4. The normal range for HE4 has recently been established in serum samples from 1101 healthy women and 67 pregnant women. HE4 concentration increased with advancing age (>40). Median serum HE4 levels in premenopausal women (46.6 pmol/L) were significantly lower than in postmenopausal women (57.6 pmol/L; $p < 0.001$). The upper 95th percentile for HE4 levels was 89 pmol/L for premenopausal women, 128 pmol/L for postmenopausal women, and 115 pmol/L for

Table 5.8 Mean Levels of Serum HE4 in Normal Controls and Benign and Malignant Lesions

Condition	Serum HE4 level (mean)
Normal Control	34.1 pM
Benign Lesions	39.1 pM
Malignant Lesions	248.7 pM

Source: Wang S, et al. The Application of HE4 in Diagnosis of Gynecological Pelvic Malignant Tumor. Clin Oncol Cancer Res. 2009; 6: 72-74.

Table 5.9 Elevations of HE4 and CA-125 in Women with Benign Disease and Ovarian Cancer

		HE4 > 89.1 pM (premenopausal women); HE4 > 128 pM (postmenopausal women)	CA-125 > 35 U/mL
Benign disease ^a	Overall (all benign tumors)	8%	29%
	Ovarian cysts	8%	14%
	Germ cell tumors (mature teratoma)	1%	21%
	Sex cord stromal tumors (thecoma, fibrothecoma)	24%	52%
	Cystadenoma, adenofibroma, cystadenofibroma	20%	20%
	Serous epithelial tumors	8%	20%
	Mucinous epithelial tumors	13%	18%
	Benign, NOS	9%	27%
	Endometriosis/endometrioma	3%	67%
	Abscess/hydrosalpinx/POD	13%	37%
	Fibroid (leiomyomas)	8%	26%
	Benign, other (Normal ovaries)	5%	22%
		HE4 > 140 pmol/L	CA-125 > 35 U/mL
Ovarian cancer ^b	Overall	75.2%	80%
	Stage I–II	58.3%	54.2%
	Stage III	78.8%	86.5%
	Stage IV	79.6%	85.7%
	Serous papillary	84.4%	84.4%
	Mucinous	43.8%	68.8%
	Other histologies	57.9%	68.5%

^bEscudero JM, et al. Comparison of serum human epididymis protein 4 with cancer antigen 125 as a tumor marker in patients with malignant and nonmalignant diseases. *Clin Chem* 2011;57(11):1534–1544.

all women. In pregnant women, median HE4 concentrations were significantly lower than their premenopausal counterparts ($p < 0.001$) (133). HE4 levels appear to be lower in the Asian population (HE4 of 33.2 pmol/L) (134). This has implication for further clinical application of the test in different populations.

Glycodelin

Glycodelin was first described as a marker with a role in OC in 2001 (135). Since then, limited studies reported evaluating its expression mainly in tissue rather than serum. Tissue expression data suggests that in serous OC, glycodelin expression carries a better prognosis (136). An ELISA-based assay was only introduced in 2005 (137). A panel including HE4, Glycodelin, MMP7, SLPI, Plau-R, MUC1, Inhibin A, PAI-1, and CA-125 evaluated in serum samples from women with OC and healthy controls showed a sensitivity ranging from 59.5% to 80.5% while maintaining high specificity. However, for detecting disease recurrence, a panel consisting of HE4, Glycodelin, MMP7, and CA-125 had a sensitivity of 100% when compared to CA-125 alone (96%) (138). Although this data is promising, further evaluation of glycodelin is required.

DNA Methylation Profile

Circulating methylated DNA may represent a new generation of tumor marker (139), as changes in DNA methylation are one of the most common alterations in human neoplasia (140). Hypermethylation of tumor-derived DNA can be found in serum and

plasma of cancer patients (141,142). Recently, in colorectal cancer the pattern of methylation of serum DNA has been shown to be a prognostic factor (143).

In OC, DNA methylation profiles have been shown to predict active disease (144), predict response to treatment (components of the WNT pathway has shown that methylation of NKD1 and DVL1 were independent predictors of progression free survival, whilst DVL1 and NFATC3 methylation were significantly associated with response to treatment) (145) and OS, as secreted frizzled-related proteins sFRP5 promoter was shown to be significantly methylated in OC and was associated with worse 5-year OS when compared to unmethylated sFRP5 (52% vs. 88%, $p = 0.03$) (146).

Salivary Transcriptomes as Novel Markers

Novel biomarker strategy, using salivary transcriptomes as possible biomarkers for OC, has been recently been evaluated in 11 OC patients and 11 controls. In a validation set of 21 OC patients and 35 healthy controls, combination of 5 biomarkers (AGPAT1, B2M, BASP2, IER3, and ILI1) yielded high sensitivity (85.7%) and specificity (91.4%) (147).

Cell-Free DNA as a Novel Marker

Cell-free DNA has increasingly been investigated as a potential biomarker reflecting the release of both normal and tumor-derived DNA into the circulation through cellular necrosis and apoptosis.

Table 5.10 Elevations of HE4 in Women with Cancers Other Than Ovarian

Cancer Group		HE4 > 140 pmol/L
Non gynecologic malignancies	Breast	5.6%
	Digestive tract malignancy	11.3%
	Small cell lung cancer (SCLC)	26.9%
	Non-small cell lung cancer (NSCLC)	29.3%
	Liver	16.3%
	Melanoma	11.1%
	Urologic malignancies	21.5%
	Hematologic malignancies	10.0%
	Mesenchymal tumours	0.0%
	Nonovarian/endometrial/NSCLC malignancies (without effusion or liver metastases)	6.5%
	Nonovarian/endometrial/NSCLC malignancies (with effusion or liver metastases)	18.5%
Non ovarian gynecologic malignancies	Endometrial cancer	28%
	Cervical cancer	0%

Source: Escudero JM, et al. Comparison of serum human epididymis protein 4 with cancer antigen 125 as a tumor marker in patients with malignant and nonmalignant diseases. *Clin Chem* 2011;57(11):1534–1544.

Preoperative total plasma cell-free DNA levels were assayed in 164 women with invasive epithelial ovarian carcinoma (EOC), 49 with benign ovarian neoplasms, and 75 age-matched controls, divided equally in training and validation set. Elevated levels of cell-free DNA were observed in OC patients, but, more notably, levels of more than 22,000 GE/mL were significantly associated with decreased patient survival ($p < 0.001$). Validation set data indicated a 2.83-fold increased risk of death from disease ($p < 0.001$) (148).

Metabolite Profiling

Metabolites are the end products of cellular regulatory processes. Alterations in their levels can be regarded as response to genetic or environmental changes. Analysis of 66 invasive ovarian carcinomas and 9 borderline ovarian tumors by gas chromatography/time-of-flight mass spectrometry (GC-TOF MS) using a novel contamination-free injector was undertaken to assess if quantitative signatures of primary metabolites can be used to characterize molecular changes in ovarian tumor tissues. A total of 291 metabolites were detected, and 114 were already annotated compounds. Principal component analysis as well as additional supervised predictive models allowed a separation of 88% of the borderline tumors from the carcinomas. The data suggests that metabolomics is a promising high-throughput, automated approach in addition to functional genomics and proteomics for analyses of molecular changes in malignant tumors (149).

MICRORNA-BASED OVARIAN CANCER BIOMARKERS

MicroRNAs (miRNAs) are noncoding RNAs that regulate gene expression by translational inhibition or mRNA degradation.

They are involved in diverse biologic processes including development, proliferation, differentiation, and apoptosis. As they encode around 3% of the genome and up to 30% of human protein coding genes may be regulated by miRNAs, they have become interesting potential biomarkers to study. Their study has also been helped by a microarray approach. In the past 5 years, several miRNA expression profiles have been published, reporting a decrease in expression in OCs compared to normal tissues. Initial studies looked at tissue profiling of ovarian cancers and normal ovaries and showed upregulation (miR-200a, miR-200b, miR-200c, miR-141) or downregulation (miR-199a, miR-140, miR-145 or miR-125b1) of certain miRNAs (150). One advantage of using miRNAs as biomarkers is that they are generally stable and can be detected in serum and plasma. More recently, 8 miRNAs extracted from serum (e.g., miR-21, miR-141, miR-200a, miR-200b, miR-200c, miR-203, miR-205 or miR-214) were compared in exosomes isolated from sera of women with benign disease and OC and demonstrated that exosomal microRNA profile in OC patients is distinct from those with benign disease (151). Resnick et al. have shown other miRNAs being up- (miR-21, miR-92, miR-93, miR-126, miR-29a) or downregulated (miR-155, miR-127, miR-99b), but more interestingly demonstrated upregulation of miR-21, miR-92, and miR-93 in 3 cancer patients with normal CA-125 levels (152). Although miRNA signature/profile is not of established value in diagnosis, prognosis, or response to treatment, further understanding of miRNA in OC is warranted.

Carcinoembryonic Antigen

CEA was first identified in 1965 in serum of rabbits immunized with colon carcinoma (153). It is an oncofetal antigen, which is found in small amounts in adult colon. Elevated levels are associated with colon and pancreatic cancer but CEA levels are also raised in benign diseases of the liver, gastrointestinal tract and lung, and in smokers. In ovarian cancer, CEA is expressed by most endometrioid and Brenner tumors and in areas of intestinal differentiation in mucinous tumors. In contrast to CA-125, this marker is not expressed in normal and inflammatory conditions of the adnexa. Around 25% to 50% of ovarian cancer patients have elevated levels of CEA and the correlation with ovarian cancer is not as well established as with the other markers (154,155).

In a small study of 21 patients, CEA, CA-19-9 and red blood cells, hematocrit, and hemoglobin were shown to be of benefit in identifying women with late stage (IB-IV) borderline ovarian tumors (156).

Preoperative CEA and CA-125 serum levels (CA-125/CEA ratio > 25) in a study of 640 patients of whom 355 had OC diagnosis, have shown a sensitivity of 82%. When the CA-125/CEA cut-off was increased to 100, specificity increased to around 85% (157).

In a tissue expression study of 189 women diagnosed with borderline ovarian tumors and 571 women with OC, using 30% as a cut-off level for CEA over-expression indicated that 18% of LMPs and 4% of OCs were positive but mucinous tumors being more likely to be positive than other histologic subtypes ($p < 0.00001$). CEA was shown to be an independent marker of prognostic value as patients with CEA expression over 30% had a shorter disease specific survival (158).

Alpha-Fetoprotein

Alpha-Fetoprotein (AFP) is an oncofetal protein produced by the fetal yolk sac, liver, and upper gastrointestinal tract. Elevated levels of AFP occur in pregnancy and benign liver disease. Serum levels are raised in most patients with liver tumors and in some patients with gastric, pancreatic, colon, and bronchogenic malignancies have elevated AFP levels (154). AFP levels were

investigated in 135 patients with germ cell tumors and elevated levels were found in all patients with endodermal sinus tumors, 62% with immature teratomas and 12% with dysgerminoma (159). AFP also accurately predicts the presence of yolk sac elements in mixed germ-cell tumors (160). Although AFP production in epithelial ovarian cancers is extremely rare, a case of ectopic production of AFP by an ovarian endometrioid tumor has been described in the literature (161).

In women with endodermal sinus tumors, AFP is a reliable marker for monitoring therapeutic response and detecting recurrence (162,163). On univariate analysis, AFP levels of over 1,000 ng/mL, age over 22, and histology were found to be major prognostic factors in 43 patients with ovarian and extragonadal germ-cell tumors (164).

Recently, a sensitive chemiluminescence (CL) imaging immunoassay method for detection of multiple tumor markers with high throughput, easy operation, and low cost was developed. The proof of concept study included 5 markers (alpha-fetoprotein, CA-125, CA-153, and CEA) to screen patients with liver, breast, or ovarian cancers. The method showed very good reproducibility, accuracy, and wide detection range, thus making it an ideal platform to study the performance of the panel in clinical and preclinical sets of samples from OC patients (165).

Human Chorionic Gonadotropin

Human chorionic gonadotropin (hCG) is synthesized in pregnancy by the syncytiotrophoblast. It is a glycoprotein hormone made up of 2 dissimilar covalently linked subunits α and β . Production of hCG by the tumor is accompanied by varying degrees of release of the free subunits into circulation. Recent advances in our understanding of hCG/hCG- β synthesis by trophoblastic and nontrophoblastic tissues alongside an improvement in techniques measuring hCG have helped define its role in the clinical practice. hCG is elevated in virtually all cases of gestational trophoblastic disease (hydatidiform mole, invasive mole, and choriocarcinoma) and serves as an ideal tumor marker. There is a close correlation between hCG levels and tumor burden and hCG levels are used in staging and clinical management. Serum hCG can also be detected in patients with nontrophoblastic cancers. Although gynecologic cancers are prominent in this group, the sensitivity of using hCG is lower than for other markers in current use except in germ-cell tumors with a chorionic component (166).

In a retrospective analysis of 113 patients with stage IC to IV malignant ovarian germ cell tumors, both on univariate and multivariate analyses, stage of disease and elevation of serum hCG- β and AFP were significant predictors of OS, whereas age at diagnosis was of no prognostic value (167). It is worth noting that this is the first study to demonstrate stage and tumor markers as prognostic parameters in patients with malignant ovarian germ cell tumors and may help in deciding on therapeutic regimen.

In a series of 424 pediatric patients with a mean age 12.5 years, tumor markers were elevated in 54% of the cases with elevated β -human chorionic gonadotropin (β -hCG), alpha fetoprotein (AFP), and CA-125 being significantly associated with malignancy ($p < 0.02$), but an elevated CEA was not ($p = 0.1880$). However, the best indicators of malignancy in these young patients were complaint of a mass or precocious puberty, a mass exceeding 8 cm or a mass with solid imaging characteristics (168).

In 2012, Lenhard et al. showed that 67% of OC and 26.7% of benign ovarian tumors had hCG-positivity in the serum with significantly higher hCG serum concentrations in patients with OC compared to benign ovarian tumors ($p = 0.000$). Ovarian cancer tissue was positive for hCG expression in 68%. Although the hCG tissue expression differed by grade, it did not by histologic subtype. Increased hCG expression was found in mucinous OCs at Stage II compared to stage I ($p = 0.018$). Although there

was no significant correlation between tissue hCG expression and overall ovarian cancer patient survival, a subgroup analysis revealed an increased 5-year survival in LH-R positive/FSH-R negative and hCG positive tumors (hCG positive 75% vs. hCG negative 50.5%) (169). LH-R has previously been shown to be of prognostic value. This study highlights that both hCG and LH-R may be useful targets in novel cancer therapies.

Muller and Cole have comprehensively reviewed the literature on hCG and its role in cancer. With regard to gynecologic malignancies, they state that the serum free β -subunit or its urinary degradation product β -core fragment is produced by 68% of ovarian, 51% of endometrial and 46% of cervical malignancies. The free β -subunit enhances growth and invasion in all these malignancies and is therefore associated with poor prognosis. However, they stress that in clinical practice, confusion arises when a patient presents with persistent low positive hCG in the absence of pregnancy and absence of obvious malignancies (170). The first aim is to rule out a tumor then consider a false positive test by assaying hCG in the urine. A further possibility in women aged over 35 with oligomenorrhea, amenorrhea or following bilateral salpingo-oophorectomy is pituitary hCG.

Inhibin and Related Peptides

Inhibins and activins are structurally related dimeric proteins first isolated from ovarian follicular fluid on the basis of their ability to modulate pituitary follicle-stimulating-hormone secretion. They are members of a larger group of diverse proteins, the transforming growth factor- β (TGF- β) superfamily, which are involved in cell growth and differentiation. Inhibin is a heterodimeric glycoprotein composed of a common α -subunit and one of two β -subunits, resulting in either inhibin A ($\alpha\beta_A$) and inhibin B ($\alpha\beta_B$), for which specific immunoassays are now available. The serum also contains immunoreactive forms of the α -subunit not attached to the β -subunit, the most abundant of which is pro- α_C and pro- α_N - α_C . The pro- α_C assay measures these precursor forms of inhibin. The original Monash assay detected immunoreactive inhibin that included a range of inhibin-related peptides in addition to biologically active inhibin dimers.

In 1989, Lappohn et al. (171) reported elevated serum immunoreactive inhibin concentration in women with granulosa-cell tumors. Numerous studies have since confirmed serum inhibin elevation in ovarian sex cord/stromal tumors and established its role in differential diagnosis and surveillance of these malignancies (172–174). The major molecular forms detected are bioactive dimeric inhibins A and B (175,176). Antimüllerian hormone, or müllerian inhibitory factor, is another member of the TGF- β superfamily that is being investigated as a marker for granulosa-cell tumor (175,177,178).

In epithelial ovarian cancer, the role of the inhibin peptides remains to be determined. Using the initial nonspecific Monash assay, elevated serum inhibin levels were reported in 25% to 90% of women with epithelial ovarian cancer (179–181). In 2004, an ELISA for total inhibin was developed (182). Tsigkou et al. investigated the sensitivity/specificity of serum total inhibin for epithelial ovarian cancer in 89 postmenopausal women with stage II to III epithelial ovarian cancer and found that patients with serous or mucinous tumors showed the highest total inhibin levels. At 95% specificity, the total inhibin assay detected 93% of serous and 94% of mucinous tumors (183). Mucinous ovarian cancers are most likely to be associated with increased inhibin levels (173,184). In contrast, using specific assays that measure bioactive dimeric inhibin A, elevated serum levels were only found in 5% to 31% of women with epithelial ovarian cancer (173,184,185). Overall, the picture is emerging that dimeric inhibin A and B levels are not informative in epithelial ovarian cancer, and total inhibin/pro- α_C immunoreactive forms are the most commonly elevated

of the inhibin-related peptides (183,185,186). Furthermore, although there is preferential secretion of precursor forms of the α -subunit rather than dimeric inhibin A by epithelial ovarian cancer, pro- α C is unlikely to be a useful marker if used alone (187). Combining pro- α C with CA-125 may improve the sensitivity for detection of epithelial ovarian cancer (185). Combination of total inhibin and CA-125 detected all cases of serous and mucinous tumors and the overall sensitivity for epithelial ovarian cancers was 99% at 95% specificity, respectively. On further follow-up, it became clear that an increase of total inhibin levels was associated with recurrence. This recent data suggest that total inhibin is a sensitive and specific marker of epithelial ovarian cancer in postmenopausal women and may therefore be combined with CA-125 for noninvasive diagnosis of epithelial ovarian cancer. Furthermore, it may also be a useful serum marker to monitor disease-free intervals (183). The elevation of inhibin in patients with ovarian malignancies is presented in Table 5.11.

In conclusion, the data suggest that functional inhibin is secreted by most ovarian granulosa-cell tumors and may be superior to estradiol in assessing therapeutic response and predicting recurrence. For epithelial ovarian cancer, dimeric inhibin A and B levels are probably not informative. While the role of total inhibin/pro- α C needs further investigation, most recent data suggests that total inhibin displays high sensitivity and specificity for serous and mucinous cancer, which is improved when total inhibin is combined with CA-125. More recently, a combination of inhibin and antimüllerian hormone has shown to be useful in diagnosis and follow-up of granulosa cell tumors (188).

Activin is a dimer of the two- β -subunits of inhibin and exists as activin A ($\beta A\beta A$), activin B ($\beta B\beta B$), and activin AB ($\beta A\beta B$). Serum activin A has been shown to be significantly elevated in epithelial ovarian cancer (175,189,190), with highest levels detected in undifferentiated tumors. High concentrations of activin A in peritoneal fluid of women with serous ovarian carcinoma has been shown to be useful in distinguishing serous ovarian cancer from cystadenoma (191). Preliminary data suggest a poor correlation of activin levels and the clinical course of the disease (175). It is possible that activin A could play a role in ovarian cancer but further investigation is needed. This may be possible with the recent introduction in 2009 of a reliable and specific ELISA for activin B (192).

Kallikreins

The human kallikrein gene family currently consists of 15 members. There is accumulating evidence that in addition to prostate-specific antigen (PSA, hK3) and human glandular kallikrein (hK2) (both prostate cancer biomarkers), many other members of the human kallikrein gene family are differentially regulated in

breast, ovarian, and testicular cancers. Recently it has been shown that the malignant phenotype of ovarian cancer cells can be enhanced by over expression of the human tissue kallikrein genes 4, 5, 6, and 7 (193). Potential biomarkers for ovarian cancer include kallikreins 5, 6, 7, 8, 10, 11, and 14 (194–197). Kallikrein 4 is upregulated in epithelial ovarian carcinoma cells in effusions (196) and kallikrein expression may have some value in differentiating ascites resulting from ovarian cancer from other malignant and nonmalignant causes (198). Human kallikrein 8 seems to be an independent marker of favorable prognosis in ovarian cancer (199), while kallikrein 7, although not an independent prognosticator for ovarian cancer, has been found to be associated with unfavorable characteristics of the disease (200). Kallikrein-related peptidase, KLK5, was found to be significantly elevated in the serum and ascitic fluid (41/41) of OC patients (42/52) with increased levels associated with poor patient outcome (201).

Osteopontin

Osteopontin is a biomarker that has been identified using gene-expression profiling techniques. The initial investigation showed osteopontin tissue expression to be weak or absent in 93% of ovarian adenocarcinomas compared to positive expression in 81.5% in borderline tumors and 50% in omental and lymph node implants. Its expression did not correlate with histologic type, grade, or clinical stage (202). In 2002, Kim et al. showed an increased expression of this marker in ovarian cancer cell lines, microdissected tissues, and plasma of epithelial ovarian cancer patients (203). Preoperative plasma osteopontin and CA-125 levels were investigated in patients with ovarian cancer, benign ovarian tumor, other gynecologic cancers and in healthy women and showed significantly higher levels in patients with ovarian cancer than the other groups. Higher plasma osteopontin levels were detected in late stage ovarian cancer patients (stage IV) and ovarian cancer patients with ascites with no correlation with histologic type. Sensitivity of preoperative plasma osteopontin in detecting ovarian cancer was 81.3%, which increased to 93.8% when combined with CA-125, suggesting that preoperative osteopontin may be a useful biomarker for differential diagnosis of ovarian cancer, particularly when combined with CA-125 (59,204). Osteopontin levels have been shown to correlate with presence of ascites, bulky disease, and recurrence (205). In predicting clinical response to therapy, osteopontin is inferior to CA-125. However, levels increase earlier in 90% of patients developing recurrent disease leading the authors to suggest that it may be useful as a complementary marker in detecting recurrent ovarian cancer (206). Recently, a study by Matsuura et al. showed that statins can inhibit OC proliferation by up to 50%, and the effect is mediated by changes in osteopontin gene expression. Simvastatin-treated

Table 5.11 Elevations in Inhibin or CA-125 Levels in Women with Ovarian Cancer

	Cancer Group	Elevations in Inhibin ^a Levels (%)	CA-125 > 35 kU/L (%)	Inhibin + CA-125 (%)
Malignant ovarian tumors	Serous	18	94	97
	Mucinous	84	71	94
	Endometrioid	54	91	90
	Other ovarian cancers	33–44	78–100	89–100
	Granulosa cell tumor	100	30	100
	All ovarian cancers	50	82	95

mice survived significantly longer compared to the controls. This is an important new area that needs further exploration in OC, as a possible new drug therapy (207).

Mesothelin

Mesothelin is a marker that was initially identified in mesotheliomas and ovarian cancers in 1996 (208). Serum levels are higher in ovarian cancer patients when compared to women with benign ovarian tumors or from the normal population. The levels increase significantly from early to advanced stages. Elevated mesothelin levels before therapy are associated with poor OS both in patients with optimal debulking surgery and in those with advanced disease (209). As mentioned previously, Schummer et al. in addition to CA-125 and HE4 examined MMP7 and Mesothelin but found that the latter two are not as useful in predicting recurrence to add to CA-125 when compared to HE4 (131). Although it is possible that mesothelin may prove to be a useful tumor marker in the future, both for differential diagnosis of epithelial ovarian cancer as well as for prognosis, there is currently little data to highlight its significance.

Cytokines

Cytokines are soluble mediator substances produced by cells that exercise a specific effect on other target cells. Their importance in tumor biology has increased since the demonstration that many cytokines are produced by cancer cells and can influence the malignant process in a positive and a negative manner (190). However, cytokines do not fulfill the classic criteria for tumor markers, as they may be elevated in a number of pathologic conditions, are invariably produced by nonmalignant surrounding tissue rather than the tumor itself and are not specific for one cell type. Despite this, their measurement in malignant conditions may provide valuable clinical information regarding prognosis and response to treatment.

Details of some of the cytokines and their role as tumor markers in ovarian malignancy are discussed shortly below. The majority are at an early stage of evaluation with conflicting reports associated with some. The most studied cytokine in the context of ovarian cancer is serum M-CSF (or CSF-1). It appears to be a marker with high specificity for ovarian malignancy with elevation being related to stage (210,211). When combined with other markers, it may have a role in ovarian cancer screening (210,212). Combination of CA-125II, CA 72-4, and M-CSF significantly increased sensitivity for detecting early-stage disease compared to CA-125II alone (70%, versus 45%) while maintaining 98% specificity (213). M-CSF may be highly sensitive and specific for malignant germ-cell tumors of the ovary, especially dysgerminoma (214). It has been shown that elevated serum levels are associated with poor outcome after adjusting for stage, grade, and degree of surgical clearance (88). In patients with advanced disease, low ascitic fluid M-CSF was associated with longer OS and was a better indicator in comparison to other prognostic factors except for zero residual disease (215). Serum M-CSF does not seem to be useful in follow-up of women with advanced disease (216).

Interleukins have also been studied in ovarian cancer. Preliminary reports demonstrated IL-6 elevation in 50% of ovarian cancer (217,218). However, combination of IL-6 and CA-125 did not improve the sensitivity of CA-125 alone (218). A further report investigating the role of CA-125, IL-6, IL-7, and IL-10 in 187 ovarian cancer patients, 45 patients with benign ovarian tumors, and 50 healthy controls found that a combination of IL-7 and CA-125 could accurately predict 69% of the ovarian cancer patients, without falsely classifying patients with benign pelvic mass (219).

Cytokeratins

Cytokeratins are intermediate filaments that are part of the cytoskeleton of all epithelial cells. They are specific markers of epithelial differentiation and continue to be expressed by epithelial cells following malignant transformation. Fragments of cytokeratins, in contrast to cytokeratins themselves, are soluble in serum and can be detected and measured using monoclonal antibodies. Their role as tumor markers in various malignancies is currently being investigated.

Tissue Polypeptide-Specific Antigen

Tissue polypeptide-specific antigen (TPS) is a proliferation marker closely related to the tumor marker TPA. It is recognized by a monoclonal antibody raised against the M3 epitope on cytokeratin 18. TPS is elevated in 50% to 77% of ovarian cancers studied, with a specificity of 84% to 85% (220–223). Preoperatively, serum levels of TPS and CA-125 were significantly higher in patients with cancer rather than benign disease and in those with advanced disease compared to early-stage disease. Similarly, levels of TPS and CA-125 were higher in malignant and benign tumor cysts and ascitic fluids than in corresponding sera with levels in cyst fluid from cancer patients being the highest (224). However, no correlation between TPS levels and survival has been shown (221). Its serial measurement may be of value in the follow-up of patients (220,221). When combined with CA-125, sensitivity for predicting recurrence of 81% was achieved with a specificity of 82% and PPV of 58% (222,223).

CYFRA 21-1

CYFRA 21-1 is a fragment of cytokeratin 19. The assay was first developed in 1993 by Stieber et al. (225). It was initially found to be elevated in cervical and endometrial cancers (226). It does not seem to be very useful in the differential diagnosis of adnexal masses, with most studies reporting sensitivities of 40% to 45% (227,228). It may have a role as a prognostic factor, but there are conflicting reports. Elevated CYFRA 21-1 levels prior to therapy were reported to be associated with poor overall and disease-free survival in ovarian cancer (228). Preoperative levels of CYFRA 21-1 were, however, higher in patients with advanced disease, but Cox regression analysis failed to detect a significant association between preoperative CYFRA 21-1 values and survival. For patients with advanced ovarian cancer, preoperative CYFRA 21-1 levels appear to be predictive of response to chemotherapy but not of survival (229). In a case report, elevated levels of CYFRA 21-1 together with neuron-specific enolase, oestradiol, and CA-125 were described in a patient with Sertoli-Leydig cell tumor of the ovary and it was suggested that it may be useful to investigate further the role of these tumor markers in individualized monitoring (230). In a study looking at a variety of other cancers, CYFRA 21-1 was found to be elevated in 19.6% of OC patients (231). There have been no further studies looking at the utility of CYFRA 21-1 measurements in OC.

Proteomics

Proteomics is the study of the expression, structure, and function of all proteins as a function of state, time, age, and environment (232–234). It complements the genomics-based approaches and has become very popular in the past decade. Surface-enhanced laser desorption/ionization time-of-flight (SELDI-TOF) analysis and matrix-associated laser desorption/ionization time-of-flight (MALDI-TOF) technologies have been employed over the past few years to identify patterns or changes in protein profile between those with and without cancer. There were numerous issues with

the study design (195,235–237) of the first OC case-control study undertaken (238). Since then a multi-center case control study has identified 3 potential serum OC biomarkers (lower levels of apolipoprotein A1, a truncated form of transthyretin, and elevated levels of a cleavage fragment of inter- α -trypsin inhibitor heavy chain H4 [ITIH4]) (239) which have been independently validated (240). More recently, various algorithms have been developed to analyze the preprocessed mass-spectrometry data and identify the most informative “common” peaks, sample handling has been fine-tuned to deliver the most promising markers (240), novel indices have been proposed (241) and the reproducibility of SELDI-derived spectra has been shown to be reasonably good as long as the data is properly processed (242). A proteomics study using preclinical as opposed to clinical samples, has shown CTAPIII and putative platelet factor 4 (PF4) to discriminate cases from controls up to 15 and 11 months, respectively, before diagnosis, but more importantly earlier than CA-125 alone (243). The technology still holds promise and is likely to deliver insightful biomarker data in the next 5 years.

Combination with Other Markers

In mucinous ovarian cancer, TATI, CA-19-9, CA 72-4, and CEA in addition to CA-125 may be of use (244). Combining CA-125 with CA 72-4, CA-15-3, and M-CSF can increase preoperative sensitivity for early-stage disease (213). The majority of studies however report limited ability to improve diagnostic sensitivity by addition of other serum markers for patients with nonmucinous tumors (112,245–248). CASA may be useful in the follow-up of patients with advanced disease in the clinic when CA-125 is inconclusive or negative (249). In CA-125-negative ovarian cancers, an immunohistochemistry profile of human kallikrein 10, human kallikrein 6, osteopontin, and claudin 3 with a smaller proportion expressing DF3 (95%), vascular endothelial growth factor (VEGF) (81%), MUC1 (62%), mesothelin (MES) (34%), HE4 (32%), and CA-19-9 (29%) may be useful but important to note that MES and HE4 exhibited greatest specificity (59). Further investigation of these markers in serum is underway.

In a study of 92 OC patients, 40 with benign disease, and 99 healthy individuals, the sensitivity of CA-125 was shown to be improved from 68% to 88% by addition of apolipoprotein A1, truncated transthyretin, and connective tissue activating protein III (250).

Combination of CA-125 and RECAF, the alpha-fetoprotein receptor, was evaluated in normal individuals and those with early (I/II) and late (III/IV) stage OC. RECAF was better at discriminating cancer and healthy individuals when compared to CA-125, especially in early stage disease (AUC = 0.96 and 0.805, respectively), with its sensitivity being high for all stages combined (251).

Other Serum Markers

Other serum markers have been assessed in isolation or as part of biomarker panels in women with OC, both in the context of screening and differential diagnosis, as well as in assessing prognosis, monitoring response to treatment and detecting recurrence. Table 5.12 details their current role in ovarian cancer. It is important to note that in women with ovarian cancer, no single marker or combination of markers has emerged with a clear clinical advantage over CA-125, except in specific tumor subtypes such as germ cell tumors with yolk sac and chorionic elements and granulosa cell tumors. The results of the proteomic and genomics studies are therefore eagerly awaited. The consensus is that these new approaches are most likely to identify novel markers or markers panels that in combination with CA-125 will improve biomarker accuracy in ovarian cancer.

ENDOMETRIAL CANCERS

There are no serum markers with an established role in the clinical management of endometrial cancer. Serum CA-125 is elevated in 10% to 31% of patients (252–255), with elevated levels detected in 63% to 67% of patients with advanced stage and 10% to 19% of those with early-stage disease (256). Preoperative assessment of serum CA-125 may be of use in predicting presence of extrauterine and metastatic disease and to a lesser extent myometrial invasion (257). It was suggested that serum CA-125 may be useful in follow-up of patients with early-stage endometrial cancer, but has not been shown to add to clinical examination and imaging (258). While distant metastases may raise CA-125 levels, isolated recurrences in the vagina do not. Levels can be falsely elevated in the presence of severe radiation injury (253). In an analysis of 97 patients with endometrial cancer, elevations of CA-125 and CA-15-3 were significantly associated with poor prognostic clinical factors. On multivariate analysis, CA-15-3 was highly significant and had a higher hazard ratio than CA-125 (255). More recent retrospective analysis of preoperative CA-125 levels in 120 patients with endometrial cancer has shown that elevated CA-125 of more than 40 U/mL was significantly correlated with higher stage, higher grade, increased depth of myometrial invasion, lymph node metastases, and the presence of lymphovascular space involvement. Women with CA-125 of less than 40 U/mL had a significantly improved 5-year OS and recurrence-free survival (RFS) rates ($p < 0.001$). The OS and RFS were highest for those with CA-125 less than 40 U/mL and without lymph node metastases, and lowest for those with lymph node metastases and CA-125 more than 40 U/mL ($p < 0.001$), suggesting that a preoperative evaluation of CA-125 may be advisable in endometrial cancer patients (259). Serial levels of CA-125 are useful in predicting recurrence in patients with high CA-125 levels at diagnosis (260).

In the 1990s, the role of a number of serum markers were explored in endometrial cancer- CYFRA 21-1 (226), urinary β -core or UGF levels (261,262), SCC and CA-15-3 (263), CA-19-9 (259), amino-terminal propeptide of type III procollagen (264), Placental protein 4 (265), CA-72-4 (266), OVX1 antigen (267), soluble interleukin-2 receptor (268), and M-CSF (252,269). However, none proved to be very useful and this is confirmed by the lack of further publications.

Higher levels of serum and plasma human kallikrein 6 in women with uterine serous papillary endometrial cancer compared to those with endometrioid carcinoma and controls without cancer (270); increased expression of inhibin β B in Grade 3 compared to Grade 2 endometrial cancer (271) and an association of matrix metalloproteinase 2 (MMP-2) expression with CA-125 and clinical course in endometrial carcinoma have been demonstrated. Positive expression of the MMP-2 and MMP-9 proteins was found in 88% and 70% of the primary endometrial cancers with positive MMP-2 immunostaining associated with a shortened recurrence-free and cancer-specific survival. MMP-2 negativity seemed linked to favorable prognosis. Preoperative serum levels of CA-125 were higher in the patients presenting with tumors positive for MMP-2 than in those with negative immunostaining (272). However, the value of such observations still remains to be determined.

More recently, a molecular biomarker study of tissue removed at curettage from Stage I and II endometrioid endometrial cancer demonstrated that combined tissue expression of survivin, p53 and p21 had a better prognostic value than classical prognostic factors (273). OC biomarkers apolipoprotein A1, prealbumin, and transferrin have been evaluated in endometrioid and serous papillary endometrial cancer and have shown a sensitivity of 71% and specificity of 88% for normal versus early stage endometrial cancer, which improved to 82% sensitivity and 86%

Table 5.12 Status of Current Tumor Markers in Ovarian Cancer

Screening		Differential Diagnosis of an Adnexal Mass		Prognostic Indicator	Monitoring Response to Therapy	Monitoring Disease and Recurrence
Epithelial cancers	Clinical practice		CA-125 is the main marker—when combined with menopausal status and ultrasound features in the risk of malignancy index (RMI), a sensitivity of 71%–85% and specificity of 96%–97% is achieved. CEA	CA-125 levels after surgery and during chemotherapy are independent prognostic indicators. Various criteria are used based on CA-125 half-life.	Serial CA-125 levels reflect clinical course in 90% of positive tumors and are used routinely for monitoring patients. HE4	CA-125 detects recurrence with a sensitivity of 84%–94% and a false-positive rate of <2%. Median lead-time compared with clinical diagnosis of recurrence is 60–99 days. HE4
	Research	Serum CA-125 being assessed in screening trials in the general (UKCTOCS) and high-risk (UKFOCSS) and trials by GOG and CGN in the USA populations. Results from PLCO reported in 2012, results from the other trials expected in 2013/14. Main emphasis on algorithms to interpret serial CA-125 and transvaginal ultrasound as a second-line test.	Inhibin pro- α C/total inhibin, kallikreins, mesothelin, prostasin, osteopontin, M-CSF, TPS, proteomic markers (profile, transthyretin, apolipoprotein A)	Kallikrein 8, mesothelin, CYFRA 21-1, M-CSF, TATI, VEGF, CASA, tetranectin HE4	CASA	Osteopontin, TPS CASA
Germ-cell tumors	Clinical practice		CA-15-3, CA-72-4, CA-19-9, TATI, GAT, free serum DNA methylation, free glycans, IL-7, TNF α receptors HE4 microRNAs metabolite profiling			
	Research		Serum AFP in tumors with endodermal sinus/yoik sac elements, serum β -hCG in tumors with chorionic elements M-CSF especially in dysgerminomas			
Sex cord stromal tumors	Clinical practice		Inhibin in granulosa-cell tumors		Inhibin in granulosa-cell tumors	

specificity when the normal endometrium samples were compared to late-stage disease (274).

Cathepsin-B and serum amyloid A have been proposed as useful markers for endometrial cancer. While increased Cathepsin-B expression was found to be predictive of more aggressive tumor behavior over time and can be regarded as an unfavorable and independent tumor marker for endometrial cancer patients with a long follow-up (275), serum amyloid A may be useful in monitoring disease recurrence and response to therapy (280).

MicroRNAs have emerged as novel cancer biomarkers and/or potential novel therapeutic targets. Their expression has been associated with tumorigenesis and tumor progression. Endometrial cancer has recently been shown to have a distinct miRNA profile with certain miRNAs demonstrating a sensitivity of 92%. In advanced disease, an miRNA pattern distinct from early-stage disease was seen, and an overexpression of miR-199c predicted improved cancer survival in this population (277). In endometrial tumors, expression of miR-26a, let-7g, miR-21, miR-181b, miR-200c, miR-192, miR-215, miR-200c, and miR-205 was evaluated and levels of miR-200c ($p < 0.0001$) and miR-205 ($p < 0.0001$) were shown to be significantly increased in endometrial tumors compared to normal tissues. The prognostic value of miRNAs was shown by a poor overall survival (hazard ratio, 0.377; Logrank test, $p = 0.028$) in patients with high levels of miR-205 expression (278). Although these findings look promising, further work on miRNA profile in serum of endometrial cancers cases is warranted.

A number of biomarkers associated with adiposity have been investigated in endometrial cancer, androgens and estrogens, insulin, glucose, IGF-1, SHBG, adiponectin, leptin, prolactin, and TSH (279).

HE4 has also been shown to be elevated in endometrial cancer. HE4, included as one of a panel of biomarkers, may be of use in risk stratification in endometrial cancer at an early stage in patients at high risk (280). In a study of 75 patients surgically treated for endometrial cancer, Kalogera et al. showed that preoperative serum HE4 levels (cut-off 8mfi) was much better at detecting advanced-stage disease than CA-125. Median HE4 was significantly elevated in both types I and II endometrial cancer compared to controls ($p < 0.001$ and $p = 0.019$, respectively). Elevated levels of HE4 were observed in type I endometrial cancer with deep myometrial invasion ($>50\%$, $p < 0.001$) and primary tumor diameter of greater than 2 cm ($p = 0.002$); however, the median HE4 was lower in lower-risk patients (type I, MI $\leq 50\%$ and PTD ≤ 2 cm) ($p < 0.01$). This new data can be of value in preoperative prediction of high-risk disease and therefore guide the need for definitive surgical staging (281).

Recent 5 years have seen a promise in identification of novel biomarkers for endometrial cancer for risk stratification and early detection. With the rising obesity across the world combined with prolonged life expectancy, it is very likely that endometrial cancer incidence will increase within the next decade. It is therefore of importance to find novel biomarkers and the novel approaches/markers shown above may demonstrate a clinical utility for risk stratification/early detection.

CERVICAL CANCERS

Screening for cervical cancer is one of the most prevalent and successful public health measures for prevention of cancer. The screening strategy is based on exfoliative cytology, liquid-based cytology, and high-risk HPV DNA detection in cervical specimens. Currently no serologic markers have been identified to be sensitive or specific enough for screening purposes. However, a variety of serum markers have been investigated in assessing prognosis, monitoring response to treatment, and detecting recurrence.

Squamous-Cell Carcinoma Antigen

In 1977, Kato and Torigoe (282) isolated the tumor antigen TA-4 from a cervical squamous-cell carcinoma (SCC). SCC is one of 14 subfractions of tumor antigen TA-4. Elevated levels of SCC are found in 57% to 70% of women with primary squamous-cell carcinoma of the cervix (283–285). The release of SCC into the circulation is independent of local tissue content, as high antigen concentrations are found in the cytosol of normal cervical squamous epithelia, but in these cases serum levels are always in the normal range (286). The antigen is not specific for cervical squamous-cell carcinoma with elevated levels found in other squamous-cell carcinomas of the head and neck, esophagus, and lung and in adenocarcinoma of the uterus, ovary, and lung. SCC levels can also be raised in skin diseases such as psoriasis and eczema (287). SCC is probably a marker of cellular differentiation of squamous cells, as the incidence of elevated serum levels is higher in women with well-differentiated (78%) and moderately differentiated carcinoma (67%) that in those with poorly differentiated tumors (38%) (286). Its levels before treatment correlate with stage, tumor volume, lymph node status, and blood vessel invasion (288–292).

In the past, there has been conflicting reports on the prognostic significance of pretreatment SCC levels (284,288,289,293–295), but increasingly it seems that a combination of pre- and posttreatment values maybe useful both for predicting prognosis and for estimating clinical response in women especially those undergoing neoadjuvant chemotherapy (295–298). On multivariate analysis of 352 patients with stage IIB-IVA squamous cell carcinoma of the cervix managed with both external irradiation and high-dose rate intracavitary brachytherapy, pretreatment SCC antigen level and lymph node metastases were found to have a significant independent effect on absolute survival and disease-free survival (299). Elevated posttreatment serum SCC levels have been shown to be indicators of treatment failure (294,298,300) and associated with poor survival rates (295). Nonetheless, the evidence is preliminary and whether pretreatment SCC level is really useful in clinical practice remains uncertain. It might be useful for individualizing treatment but no randomized trials have yet been conducted to confirm this hypothesis. There is no evidence that more aggressive treatment improves pelvic control and survival in patients with elevated SCC levels (301).

In serum SCC-positive patients, serial measurements correlate with clinical course of the disease (302,303). Raised SCC levels were found in 50% to 71% of patients with recurrent carcinoma, with a lead-time ranging from 0 to 12 months (283,304). This suggests it may be useful for monitoring disease after primary treatment. However, there is as yet no evidence that earlier detection of recurrent disease influences treatment outcome or prognosis after primary treatment.

Preliminary studies suggest that SCC antigen (SCCA) isoforms may provide additional clinical information when compared to total SCCA. Roijer et al. developed and evaluated specific serum immunoassays for the different forms of SCC antigen (free SCCA2, total SCCA2, total SCCA1, and total SCCA). Patients with recurrence or progressive disease had rising levels of SCCA1 and SCCA2, with elevations in SCCA2 being more prominent than that in SCCA1 (305).

In conclusion, SCC may prove useful in the pretreatment identification of squamous cervical cancer patients at high risk of lymph node metastasis, pretreatment prediction of prognosis, monitoring response to treatment and detecting recurrence. However, further studies are needed before clinical recommendations can be made.

CYFRA 21-1

Following detection of elevated levels of CYFRA 21-1 in patients with squamous-cell carcinoma of the lung, various groups started

investigating its role in cervical carcinoma. Tsai et al. detected elevated CYFRA 21-1 levels in 14% of controls, 35% of patients with stage IB-IIA squamous-cell carcinoma of the cervix, and 64% of patients with stage IIB-IV disease (306). Although CYFRA 21-1 was related to tumor stage and size in patients with cervical cancer (307) and there was a positive correlation with SCC, its sensitivity and specificity for detection of squamous-cell carcinoma of the cervix were lower than SCC (306,308,309). In cervical adenocarcinoma, it was elevated in 63% of patients (309). CYFRA 21-1 may have a role in follow-up of women with cervical cancer (310). In the study by Pras et al. (298) elevated CYFRA 21-1 levels after chemoradiation for cervical cancer indicated residual tumor in 70% of patients. Nonetheless, the evidence available so far does not justify the routine measurements of these markers.

CA-125/CEA

Serum CA-125 is only elevated in 13% to 21% of women with squamous-cell carcinoma (302,311). It is a better marker than SCC for cervical adenocarcinoma (302,311,312). In combination with CA-19-9, a sensitivity of 60% for cervical adenocarcinoma was reported with the addition of CEA to this combination increasing sensitivity to 70% (313). Elevated CA-125 levels have been found to contribute to prognosis (314,315), with levels falling in women who respond to chemotherapy (316). In adenosquamous cervical cancer, serum CA-125, SCC, and CEA were found to be elevated in patients with progressive disease, whereas only CA-125 was elevated in women with adenocarcinoma (312). Serum CEA alone is less useful in cervical cancers, with an overall sensitivity of 15% and specificity of 90%. Patients with cervical adenocarcinoma have significantly higher levels of CEA than those with squamous cell cancers (317).

More recently, methylation markers have been evaluated in cervical cancer. A study by Gokul et al. showed that the DNA methyltransferase (DNMT3L) promoter had lost DNA methylation to varying levels in 14 out of 15 cancer cervix samples. This not only shows a promising role of DNMT3L as biomarker in cervical cancer but also provides insight into its possible role in cancer development (318).

In screening context, a number of biomarkers have been evaluated—Ki-67, p16INK4A, BD ProEx C (containing antibodies to the nuclear proteins minichromosome maintenance protein 2 [MCM 2] and topoisomerase II alpha [TOP2A] and Cytoreactiv HPV L1) (319)—which may not only be able to triage mildly abnormal and indeterminate cytology cases but also identify those with high-grade disease. One of the panel, p16(INK4a), is one of the better studied markers that has been shown to be substantially overexpressed in virtually all HPV-transformed cells, thus improving the accuracy of cytology-based cancer early-detection programs (320).

It is anticipated that the introduction of prophylactic HPV vaccines will reduce the incidence of cervical cancer and its malignant precursors, therefore focusing effort on identifying the women most at high risk who would then require treatment, as well as improving the triage of the HPV-positive tests. It is believed that biomarkers will also serve an important role in the optimization of this alternative screening algorithm; therefore, efforts continue to identify the best-suited biomarkers for this purpose.

More recently, circulating cell-free nucleic acids have emerged as a novel class of markers for cancer detection. Circulating Bmi-1 mRNA was put forward as a potential noninvasive molecular

marker for diagnosis and prognosis of cervical cancer. Zhang et al., in plasma samples of 109 patients with cervical cancer, 138 patients with cervical intraepithelial neoplasia (CIN), and 80 healthy volunteers, found a correlation between increased circulating Bmi-1 mRNA level and reduced disease-free survival (DFS) ($p = 0.001$) and OS ($p = 0.015$). Circulating Bmi-1 mRNA was an independent prognostic factor for DFS and OS (321).

DNA methylation markers may be useful in detecting cervical cancer metastasis. Methylation of the protein tyrosine phosphatase receptor type R (PTPRR) promoter has an important role in metastasis and may be a biomarker of invasive cervical cancer (322).

VULVAR AND VAGINAL CANCERS

Tumors of the vulva and the vagina are rare, and there are relatively few studies on circulating markers in these conditions. TPS has been shown to be elevated in 80% of patients with vulvar or vaginal cancer (220), whereas SCC levels were elevated in 43% (323). Carter et al. (324) studied urinary core fragment of the β -subunit of hCG in these cancers. Although the sensitivity of β -core was only 38%, a highly significant difference was observed in the survival curve between those with elevated β -core levels compared to those with normal levels. Ninety percent of patients with elevated levels died within 24 months in contrast to 32% of those with normal levels. It might also be useful in detecting recurrence, as rising UGF levels at an earlier clinic visit predicted recurrence in four of seven patients. These data, albeit limited, suggest that for lower genital tract malignancies, the measurement of urinary β -core may be valuable as prognostic indicator, allowing a more informed approach to treatment and in follow-up.

CONCLUSIONS

The potential role of serum tumor markers is hampered by the fact that these markers are neither confined to the malignant tumor cell nor limited to the malignant phenotype. Of all the markers available in gynecologic malignancies, serum hCG in gestational trophoblastic disease remains closest to the ideal tumor marker. Serum CA-125 continues to be the most useful clinical marker in OC with an established role in diagnosis and monitoring whilst HE4 shows promise as a complementary marker. Progress in understanding the origin of ovarian cancer may lead to identification of more promising markers that would distinguish Type II from Type I OCs, with implications for screening and differential diagnosis, as well as prognosis and monitoring treatment response. The results of the UKCTOCS trial of screening involving CA-125 and ultrasonography are awaited to clarify the role of OC screening.

Novel biomarkers, identified through proteomics and genomics, are undergoing validation studies and along with developments in metabolomics, DNA methylation, and novel transcriptome and microRNA markers may lead to further candidates that can be used either alone or in combination with existing tumor markers.

Cancer Prevention Strategies

MARY B. DALY

INTRODUCTION

As our knowledge of the genetic, physiologic, environmental, and lifestyle factors associated with the carcinogenic process grows, the prevention of cancer is increasingly becoming a reality and being incorporated into oncology practice. Options for the primary prevention of cancer are expanding and include avoidance of carcinogens (e.g., smoking cessation, sun avoidance, removal of asbestos), diet modification, exercise, and weight loss, use of cancer vaccines, prophylactic surgery, and chemoprevention. It is estimated that avoidance of tobacco, sun exposure, and elimination of obesity could have a major public health impact on cancer incidence, as well as other chronic conditions. Options for secondary prevention through screening for occult disease when treatment may be more effective are also becoming more sophisticated. Great strides have been made in the prevention of many of the most common cancers.

The most common risk factor for lung cancer, which is the largest cause of death from cancer for both men and women, is tobacco use. Primary prevention strategies, including tax increases on tobacco products, restrictions on smoking in public places, and the physiologic and psychologic treatment of nicotine addiction have all contributed to the reduction in smoking prevalence rates and the decrease in the incidence of lung cancer (1,2). Recently, low-dose spiral CT scans have been shown to detect early-stage lung cancer and result in a reduction in lung cancer mortality (3,4).

Nonsteroidal anti-inflammatory drugs reduce the risk of adenomatous polyps and invasive cancer among individuals with very high risks of colon cancer due to hereditary syndromes (5). Their use for primary prevention among individuals at average risk, however, is not recommended due to potential side effects. Perhaps the greatest contribution to the prevention of colorectal cancer is the increasing adoption of screening colonoscopy to identify and remove premalignant polyps (6).

Large randomized trials have established the efficacy of both tamoxifen and raloxifene to prevent estrogen receptor positive breast cancer (7,8). With the demonstration of the increased risk in breast cancer associated with combined estrogen and progesterone hormone replacement therapy by the Women's Health Initiative, the use of these products has declined significantly, and the decline is thought to be associated with a subsequent decrease in breast cancer incidence (9,10). Both prophylactic mastectomy and prophylactic oophorectomy reduce the risk of breast cancer and are considered options for women with hereditary syndromes that convey high rates of breast and ovarian cancer (11). Advances in screening modalities for breast cancer, including the increasing adoption of digital mammography and the use of screening breast MRI in selected high-risk individuals

has improved the detection of early-stage occult cancers, and has led to a down staging of disease (12,13).

A large randomized trial of finasteride, which reduces the androgenic stimulation of the prostate, produced a 25% reduction in prostate cancer incidence (14). Several other agents have been proposed as chemopreventive agents for prostate cancer, but so far none have proven efficacy. The role of prostate cancer screening with digital rectal exam and serum PSA levels among average risk men has recently been challenged (15). The role of screening high-risk men, African American men and those with a family history of this cancer, is the subject of ongoing studies.

The prevention of gynecologic cancer is becoming a reality due to the recognition that the initiation and progression of gynecologic cancers is a multistep process characterized by distinct molecular genetic events that provide opportunities to intervene in the carcinogenic process at several steps and reverse its early stages. The concept of preventing gynecologic cancer is based on an understanding of causally related risk factors, their role in carcinogenesis, and opportunities for their avoidance and/or reversal of their effect. There are 3 distinct models that can be applied to gynecologic cancer prevention: (a) *risk avoidance and adoption of protective practices* includes the identification of key risk factors and the development of strategies for their avoidance. Included in risk avoidance are the avoidance of exogenous and endogenous exposures (chemical, hormonal, infectious, etc.) and the avoidance of risky health behaviors. The adoption of protective practices, such as vaccination with the human papillomavirus (HPV) vaccine, a healthy diet, and exercise, may forestall early premalignant events; (b) the use of *chemopreventive agents*, both natural and synthetic, to reverse early, premalignant changes; and (c) *surgical prophylaxis* to remove either healthy at-risk organs or tissues with premalignant changes.

In addition to establishing valid interventions for cancer prevention, it is important to identify optimal target populations for their application, and to tailor the interventions to the level of risk. Interventions for use in the general population at average risk must be highly effective, safe, inexpensive, and socially acceptable. Population groups with high risks may tolerate interventions that confer more risk and higher costs. All prevention efforts are greatly enhanced by public and professional education about their use and by a health care system that values, promotes, and invests in prevention activities.

The avoidance of environmental, occupational, and lifestyle risk factors through public education and social policies has the potential to prevent a large proportion of human cancer. The epidemiological literature has provided a wealth of information about the risks associated with cancers of the cervix, uterus, and ovary, which allows us to devise risk avoidance and risk reduction strategies. This chapter focuses on the opportunities for primary prevention of these three cancers and directions for the future.

CERVIX CANCER

Risk Factors

There are approximately 13,000 new cases of cervical cancer per year in the United States, and over 4,000 women die of the disease. The disease burden is not distributed equally but is overrepresented in the United States among African American, Hispanic/Latina, and American Indian women (16). The greatest burden of cervical cancer is in the developing countries (Fig. 6.1), which account for 86% of the cases and 88% of deaths (17). Traditionally, the most significant factor associated with the risk of cervical cancer has been number of sexual partners and the early onset of sexual activity. This observation has led to the discovery that the primary cause of cervical cancer, and its precursor, intraepithelial lesions, is persistent infection with HPV, which is sexually transmitted. The HPVs are a large (over 100 types) family of viruses that infect skin and mucosa (Fig. 6.2). Of the approximately 40 HPV types that infect the genital tract, about one-half are associated with anogenital warts and are considered low risk for malignancy, or nononcogenic. The other half may give rise to a range of anogenital cancers, including cervix, vulva, and anus in women, and penis and anus in men, and are referred to as high-risk or oncogenic (18). HPV types 16 and 18 alone account for >70% (Fig. 6.3) of all cervical cancers. Similarly, HPV types 6 and 11 account for >90% of all anogenital warts. In the United States, where the median age of sexual debut is 17 years, close to 20% of girls are sexually active by age 15 years, and close to 60% are sexually active at age 18 years. As a result, the infection rate of HPV among the general population is high, peaking in the second and third decades of life when infection rates range from

27% to 46% (19). The median length of infection is 8 to 12 months, and most individuals have cleared the virus by 2 years. A small proportion, 10% to 13%, however, develop chronic persistent HPV infection, which can lead to genital warts, cervical dysplasia, carcinoma *in situ*, and invasive cancer (Fig. 6.4). Persistence of HPV infection is likely to be related to modifying factors, including immune status, the use of oral contraceptives (OCP), smoking, and infection with other sexually transmitted diseases (20). Prolonged duration of OCP use is thought to function as a promoter of HPV-related carcinogenesis, not as a facilitator of HPV infection, although the mechanisms are uncertain (21). Tobacco carcinogens have been found in cervical secretions, and it is postulated that smoking constituents may interact with HPV to induce immunologic changes leading to cervical dysplasia, or may produce genomic damage via genotoxins (22,23).

The HPVs are nonenveloped, double-stranded DNA viruses whose circular DNA encodes eight genes, six early genes, which encode nonstructural proteins (E1, E2, E3, E4, E5, and E6) responsible for viral replication and transcription, and two late genes (L1 and L2), which encode the structural components of the viral capsid. HPV can infect the basal cells of the cervical epithelium and replicate in an extrachromosomal form. In HPV-related malignancy, the virus can integrate into cellular DNA and interact with p53 and RB (retinoblastoma), which prolongs the cell cycle, inhibits apoptosis, and can result in malignant transformation (24). Another potential mechanism for carcinogenesis that has been observed in HPV-16-infected cells is aberrant mitotic spindle pole formation resulting in genetic instability (25). The recent production of prophylactic vaccines that induce the generation of neutralizing antibodies to certain oncogenic types of HPV, therefore, represents a major breakthrough in the prevention of cervical cancer.

Prevention

Risk Reduction and/or Adoption of Healthy Practices

Cervical cancer prevention requires decreasing the risk of infection with oncogenic strains of HPV. Having few sexual partners and the use of condoms have been associated with a reduced risk for cervical cancer (26). Avoidance of those factors that enhance the persistence of HPV infection, viz. smoking and OCP use, has the potential to reduce the rate of malignant change. OCPs, however, are the most effective means of contraception, and their avoidance overall is not a wise public health strategy. Safe and effective vaccines now offer the best option for cervical cancer prevention. Early studies in animal models provided

the proof of principle that neutralizing antibodies, directed to determinants on the major viral capsid protein, were generated by infection with HPV and could be detected in the serum. In the early 1990s it was found that the L1 protein, when expressed in recombinant vectors, self-assembled into virus-like particles (VLPs), which closely resemble the antigenic characteristics of the wild-type virions. VLPs formulated on aluminum adjuvants were shown to induce a strong virus-neutralizing antibody response in nonhuman primates (27,28), leading to their development for human populations. A series of phase 1 trials in humans tested the immunogenicity and safety of monovalent VLP-based vaccines and found that they generated levels of neutralizing antibodies that far exceeded those seen in natural infections, and were sustained at long-term follow-up. The predominant antibody responses are of the immunoglobulin G1

(IgG1) subclass (18). In these early trials, vaccine efficacy against infection with HPV-16/18 and against CIN 2+ at 6.4 years of follow-up was 100% (29).

Subsequently, 2 vaccines have been developed for use in humans, Gardasil (Merck), a quadrivalent vaccine that includes HPV-16, -18, -6, and -11 and is formulated with aluminum adjuvant, and a bivalent vaccine Cervarix (GlaxoSmithKline), which includes HPV-16 and -18 and is formulated with a proprietary adjuvant, AS04, which contains aluminum and a bacterial lipid. Gardasil has undergone several randomized, placebo-controlled trials among over 21,000 women. In a U.S. multicenter proof of principle study, 2,391 young women aged 16 to 25 were assigned to a monovalent yeast-derived HPV-16L1 VLP, formulated on aluminum adjuvant, by intramuscular injection at day 0, month 2, and month 6 or placebo. The primary outcomes were persistent HPV-16 infection and HPV-16-related carcinoma *in situ* CIN 2 and 3. At a follow-up of 48 months, administration of the three-dose regimen of HPV-16 vaccine resulted in a 94% reduction in persistent HPV infection in those treated according to protocol. The vaccine was 100% effective in protecting against HPV-16-related CIN 2 and 3 (30).

A phase 2 dose-ranging assessment of immunogenicity and efficacy was conducted in the United States, Brazil, and Europe among 552 women aged 16 to 23 years. Women were randomized to 1 of 3 vaccine doses versus placebo given at day 1, month 2, and month 6. At close to 3 years of follow-up, vaccine efficacy for reduction of persistent HPV infection was 90% and for clinical disease (cytologic abnormalities, CIN, cervical cancer, or external genital lesions) was 100%. Vaccine efficacy was similar for each of the three doses. All women who received the vaccine developed high antibody titers by month 7 (31). Early data on vaccine efficacy found similar results with 2 versus 3 doses, which if borne out, is likely to improve compliance (32).

The two pivotal phase 3 trials enrolled more than 18,000 women and included both precancerous lesions, CIN 2, CIN 3, adenocarcinoma *in situ* (AIS), or invasive cervical cancer with documented HPV-16 or -18 in DNA from the involved tissue, vulvar and vaginal lesions, and genital warts as outcomes. Women with evidence of previous infection with HPV, or with cytologic abnormalities, were not excluded. At 3 years, vaccine efficacy in those women treated according to protocol was 99%, with only one case of CIN 3 occurring among the vaccine recipients. In the intent to treat population, which included women with prevalent HPV-16/18 infection and women who did not complete the vaccination schedule, CIN 2/3 and AIS were reduced by 44% (33,34). The vaccine was also efficacious against high-grade vulvar and vaginal lesions (35). To

investigate the efficacy of Gardasil among older women, 3,891 women aged 24 to 45 years were randomized to vaccine or placebo. Efficacy against persistent infection and cervical lesions was 89% (36). Side effects in all of the studies were minimal and included discomfort at the injection site and occasional mild fever. Anti-HPV antibody titers remain high 5 years after administration. In June 2006, Gardasil received FDA approval for the vaccination of women aged 9 to 26, followed closely by approval for its use in children and adults aged 9 to 26 years by the European Commission.

The initial trial of Cervarix randomized 1,113 women aged 15 to 25 years to receive a bivalent HPV-16, -18 vaccine versus placebo. No cases of persistent HPV-16 or HPV-18 were seen in the women vaccinated according to protocol, whereas there were seven cases of infection in the control group. The vaccine was 95% effective against persistent infection and 93% effective against cytologic abnormalities even when including those women who did not complete the vaccine regimen. In an extended follow-up of 776 women, the vaccine continued to demonstrate 98% efficacy at close to 4 years (37,38). The Papilloma TRIal against Cancer In young Adults (PATRICIA) randomized 18,644 women to 3 doses of Cervarix versus hepatitis A vaccine. At a mean of 34.9 months follow-up, HPV vaccine efficacy, assessed in women who were seronegative DNA for HPV-16/18 at baseline, against CIN 2+ lesions was 92% (39).

There was also efficacy against CIN 3+, especially in the 15- to 17-year age group (40). Furthermore, the vaccine provided cross-protective efficacy against 4 oncogenic nonvaccine types: HPV-33, HPV-31, HPV-45, and HPV-51 (41).

Overall, achieving close to 100% effective vaccination of a cohort of 12-year-old girls is estimated to result in a 76% reduction in the incidence of cervical cancer (42). Mathematical modeling has been used to estimate the clinical benefits and cost-effectiveness of a population-based HPV-16/18 vaccination program in Africa (Fig. 6.5). Parameters considered were the natural history of HPV and cervical cancer, age at vaccination, vaccine cost, vaccine efficacy, waning immunity, the risk of replacement with other oncogenic strains of HPV, age at onset of screening, and screening intervals. A review of 27 studies of cost-effectiveness models found considerable variability in the incremental cost-effectiveness ratios (ICER) due to the different assumptions made. Overall, however, the implementation of routine vaccination programs for adolescent girls is consistently shown to be cost-effective compared to screening alone (43). The Advisory Committee on Immunization Practices (ACIP) of the Centers for Disease Control and Prevention (CDC) recommends routine vaccination for HPV of girls age 11 to 12 (range, 9 to

FIGURE 6.5. Impact of HPV-16/18 vaccines on incidence of cervical cancer.

26 years) and has added Gardasil to its Vaccines for Children program (44,45). Similarly, the American Academy of Pediatrics recommends that all girls should be vaccinated against HPV at age 11 to 12 years (46).

Both Gardasil and Cevaxix are licensed for use in the United States for girls aged 11 to 12 years, with catch up vaccination up to age 26 years. Immunogenicity of both vaccines is close to 100% (47).

There are several questions remaining regarding the use of HPV vaccines. The duration of protection afforded by HPV vaccines is not known, although data from animal models report long-lasting protection even with low levels of circulating antibody. Evidence from recent clinical trials in humans suggests persistence of immunity beyond 4 years. The need for a booster dose is at this time unknown. Because the neutralizing antibodies generated by the current vaccines appear to be type specific, it is not clear if there is cross-reactivity with other HPV types. It is also unclear whether vaccinating an adolescent population will be socially acceptable in all cultures. Most of the randomized trials performed to date focused on young women in their late teens and early 20s, an age when sexual activity has likely already begun. Because HPV vaccines are ineffective after infection with HPV, vaccination should occur prior to the onset of sexual activity, or at a younger age. The majority of females will become infected with HPV within 2 to 3 years of the onset of sexual activity. Depending on socio-cultural variations in sexual debut, the target age for vaccination would ideally be girls aged 9 to 12 years. There is currently no systematic vaccination program beyond infancy and preschool in the United States. Although vaccinating older women who are uninfected with HPV has been shown to induce an effective immune response (36), studies have shown that antibody response is higher among younger age groups (30,48).

Another unanswered question is the added benefit of vaccinating males. Although the majority of morbidity associated with HPV is seen in females, males remain the major vector for the disease. Furthermore, both males and females would need to be vaccinated to achieve herd immunity. Information on the natural history of HPV in males is lacking, and vaccination studies to date have focused predominantly on females. One Phase III study of Gardasil in men reported a 90% reduction in HPV-associated external genital lesions (32). Among women, the impact of effective vaccination on subsequent screening practices is not known. There is concern that women who receive the HPV vaccine might be less likely to adhere to screening guidelines because they feel protected from cervical cancer. Women who have been vaccinated will, however, need to continue cytologic screening since the current vaccines do not protect against all oncogenic types, and since some women will have already been infected at the time of vaccination. It is likely, however, that the onset of screening could safely be delayed. Concerns about the impact of HPV vaccination on the subsequent accuracy of cytologic screening have also been raised.

Much work remains to be done to educate the public about HPV and cervical cancer. Recent studies have shown that the majority of women are unaware of the link between HPV and cervical cancer. Awareness of HPV is increased among young women, more educated women, and those with more access to the health care system (49,50). Public health efforts to introduce the vaccine will clearly need to be accompanied by vigorous educational programs directed at both young women and their parents to increase acceptability and the success of the HPV vaccine program. Since the introduction of Gardasil into clinical care, there has been vigorous debate about the issue of compulsory HPV vaccination. Concerns raised include the lack of long-term safety data, the expense of the vaccine, and resistance to governmental coercion (51). Another concern that parent and other groups have expressed is the fear that vaccination against HPV may lead to a sense of invulnerability, would undermine

abstinence-based messages, and may increase high-risk sexual behavior. There is no data, however, to suggest that fear of HPV is an important deterrent from sexual activity in young men or women. Several states have considered legislation to mandate HPV vaccination, although few have actually enacted such laws. All of the proposed laws have opt-out provisions for parents who object. However, they do not address the potential financial burdens imposed by the mandate. Mandating HPV vaccination would certainly boost vaccine coverage rates, but at a price of loss of parental autonomy.

These and other vaccine-related concerns will need to be addressed by primary care providers as well as public health officials. Vaccine delivery by primary care practitioners in the United States is approximately 32% among 13- to 17-year-old girls. In contrast, rates of vaccination completion in the UK and Australia, where vaccine programs are school-based, are much higher ($\geq 84\%$ and $\geq 72\%$, respectively) (52).

The most significant unresolved issue pertains to the application of HPV vaccines to underdeveloped nations, where the greatest burden of disease attributable to HPV is found (Fig. 6.5). Contributing to this burden is a lack of understanding of the dimensions of the disease, weak infrastructures and insufficient funds for population-wide vaccination programs, and a lack of the political will to address a sexually transmitted disease. The delivery of a new vaccine to a nonpediatric population is particularly problematic in countries with limited public health resources. Yet it is precisely in these countries that the potential benefit for a widespread vaccination program is greatest. Administering the vaccine in infancy along with other basic childhood vaccines may be the best choice, even though the duration of protection is at this time unknown. Clearly, the contribution of the international community will be required to make HPV vaccination a reality in the third world.

Chemoprevention

Several promising targets for the chemoprevention of cervical cancer have been identified, including topical retinoids, carotenoids, prostaglandins, indole-3-carbinol, green tea, and immune modulators (53,54). In phase 1 and 2 trials, topical retinoids applied directly to the cervix resulted in significant complete histologic regression of CIN 2 lesions compared to placebo (55). None of the proposed agents, however, have been subject to definitive phase 3 randomized trials.

Surgical Prophylaxis

The introduction of widespread cervical cancer screening using the Papanicolaou (Pap) smear has dramatically reduced the incidence of invasive cervical cancer through the detection of treatable, premalignant lesions, referred to as cervical intraepithelial neoplasia (CIN). Recently, the detection and quantification of oncogenic HPV DNA in cervical epithelial cells has been added to routine Pap screening in selected situations, with demonstrated improvement in sensitivity. Cotesting with HPV DNA detects high-grade lesions earlier, thus providing a subsequent longer low-risk period (56). HPV screening is recommended in women with atypical squamous cells of undetermined significance (ASCUS) on cytology, cotesting with cytology in asymptomatic women aged 30 and older, among whom a positive HPV screen is thought to represent persistent infection, and in follow-up of treated individuals for more aggressive detection and management of persistent HPV infection (19,57). Its use in asymptomatic women under the age of 30 leads to overdiagnosis because of the transient nature of infection in this age group. Studies of cost-effectiveness of cotesting with HPV DNA and cytology offer a cost saving by allowing for a reduction in the frequency of screening (58).

Transient HPV infections are associated with low-grade lesions (CIN 1). When oncogenic HPV infections persist, the

Table 6.1 Cervix Cancer—Major Points

Virtually all cervix cancer is related to persistent infection with HPV

HPV infection is common, affects up to 50% of women, and peaks in the second and third decades of life

Altered immune status, smoking, and the use of OCPs affect the rate of persistent HPV infection

Cervical cancer is a leading cause of cancer morbidity and mortality among women in the underdeveloped world

Two HPV vaccines have shown high efficacy in eliminating persistent HPV infection and cervical lesions in previously uninfected women

viral genome is integrated into the host genome and cervical lesions progress to more advanced lesions (CIN 2 and VIN 3) (57). Because of the high rate of spontaneous regression, management of women with CIN 1 and satisfactory colposcopy (visualization of the entire squamocolumnar junction) is repeat cytology at 6 and 12 months or DNA testing for oncogenic types of HPV at 12 months. Alternatively, ablative (cryotherapy, electrocoagulation, or laser vaporization) or excisional (cold-knife conization or loop electrosurgical excision procedure [LEEP]) treatment may be offered. If the entire squamocolumnar junction cannot be visualized, an excisional procedure is the preferred approach. Treatment of CIN 2-3 lesions with satisfactory colposcopy involves excision or ablation of the entire transformation zone rather than just the colposcopically identified lesion (59). Cryotherapy, laser vaporization, and LEEP all appear to be effective modalities, although over time LEEP has become the procedure most widely chosen. When colposcopy is not satisfactory, a diagnostic excisional procedure is recommended. A variety of posttreatment surveillance protocols utilizing cervical cytology with or without colposcopy and HPV testing at frequent intervals have been proposed. Hysterectomy is reserved for recurrent or persistent biopsy-confirmed CIN 2-3, for positive margins when repeat diagnostic excision is not possible, or for women with persistent CIS who have been previously treated and who no longer desire fertility (60). This approach to cervical cancer prevention based on large-scale cytologic screening programs is not feasible, however, in countries in the developing world, due to lack of infrastructure, funding, and public health education (Tables 6.1 and 6.2).

Table 6.2 Cervix Cancer—Remaining Questions

What is the duration of protection of HPV vaccines?

What is the extent of cross-vaccination with the current HPV vaccines?

What is the socio-cultural acceptability of vaccinating adolescent girls?

What is the added benefit of vaccinating males?

What is the impact of effective vaccination on subsequent screening practices and screening performance?

Which methods will best educate the public about HPV vaccines?

How should HPV vaccines be made available to underdeveloped nations?

What are the best cervical cancer screening approaches for use in the underdeveloped countries?

HPV, human papillomavirus.

OVARIAN CANCER

Risk Factors

Ovarian cancer is the most common cause of death from a gynecologic cancer in the United States and accounts for approximately 15,500 deaths per year (16). Worldwide there are 192,000 new cases per year. Ovarian cancers are categorized as serous, endometrioid, clear cell, and mucinous. These categories are further divided into high-grade and low-grade. High-grade serous cancer represents the majority of epithelial ovarian cancer (70%) (61). Due to a lack of effective screening tools to identify ovarian cancer at early, highly curable stages, the majority of ovarian cancers are diagnosed at advanced stages when survival is poor. Historically, the origin of epithelial ovarian cancer was believed to be from the invagination of ovarian surface epithelium (OSE) into the ovarian stroma forming inclusion cysts, which had the potential to undergo malignant transformation (62). The recent adoption of prophylactic salpingo-oophorectomy for women with deleterious mutations in *BRCA1* and *BRCA2*, however, has challenged that theory. Careful examination of the fallopian tubes obtained at the time of prophylactic surgery has identified a high prevalence of occult primary serous carcinomas and serous tubal intraepithelial carcinomas (STIC) in the fimbrial end of the fallopian tube. Both lesions are often accompanied by p53 mutations, suggesting that STIC is the precursor lesion for invasive ovarian carcinoma. While these changes were originally thought to be present only in women with *BRCA1* or *BRCA2* mutations, there is growing evidence pointing to the existence of these precursor lesions among women who develop sporadic serous ovarian cancer (63). The distal fallopian tube, therefore, is increasingly being seen as the origin of tubal, ovarian, and peritoneal serous ovarian cancer. The fallopian tube is also implicated in the presentation of endometrioid and clear cell ovarian cancers, which are attributed to the passage of endometriosis tissue from the uterus through the fallopian tube to implant on the surface of the ovary or the peritoneum where it can undergo malignant transformation (64).

While our understanding of the biology of epithelial ovarian cancer is rapidly advancing, most of our current knowledge regarding risks for ovarian cancer has emerged from the epidemiologic literature. Advancing age, reproductive factors (specifically, nulliparity), and heredity are established risk factors for the disease. The majority of ovarian cancers are diagnosed after menopause. Rates are higher in nulliparous women, while parity has been found to offer protection. The risk of ovarian cancer is increased twofold in women who are infertile, and the risk appears to be independent of fertility drug treatment (65). Chronic inflammation, with its attendant increase in cell proliferation and potential for DNA disruption, has been proposed as a precursor for many cancers, including ovarian cancer. Endometriosis and pelvic inflammatory disease, both of which induce chronic inflammatory states, are associated with ovarian cancer (64).

Although the majority of cases of ovarian cancer are sporadic, approximately 5% to 10% are thought to fit a hereditary pattern of autosomal dominant inheritance. Epidemiologic studies have estimated a two- to fourfold increase in risk among first-degree relatives of women with ovarian cancer. Recently, a number of genes have been identified that account for a large percentage of hereditary ovarian cancer and that allow more precise estimates of risk. Since the identification of *BRCA1* on chromosome 17q in 1994, and *BRCA2* on chromosome 13q in 1995, several hundred mutations in these genes have been characterized, many of which lead to premature truncation of protein transcription and, therefore, presumably defective gene products. Ovarian cancer in these families is characterized by multiple cases of ovarian and breast cancer in successive generations, earlier age of onset, and evidence of both maternal and paternal transmission (Fig. 6.6). The penetrance of *BRCA1/2*,

of ovarian cancer provides new opportunities to understand the biology of the disease and to devise novel preventive strategies.

Prevention

Risk Avoidance and/or Adoption of Protective Practices

The available evidence regarding factors that lower ovarian cancer risk has been based primarily on the results of case-control studies retrospectively comparing the reproductive, hormonal, or behavioral characteristics of ovarian cancer cases with matched controls, not on prospective randomized trials. These studies have consistently shown an inverse association of ovarian cancer with increasing parity, with the first birth conferring significantly more protection (35%) than subsequent births (15%). The protective effect of pregnancy occurs regardless of fertility history and is not age dependent (68). Pregnancy is characterized by a prolonged period of anovulation as well as high levels of circulating progesterone, which may cause terminal differentiation of premalignant cells (69,70).

The evidence supporting a protective effect of breast-feeding against epithelial ovarian cancer risk is weak and inconsistent. Some studies suggest a 10% to 20% decrease in ovarian cancer risk associated with breast-feeding. In those studies that are positive, the impact of breast-feeding on ovarian cancer risk appears to be greatest for the first 6 months of lactation with no apparent increase in ovarian cancer protection with longer-term lactation (71,72).

Several studies have examined the association of hormone replacement therapy (HRT) with ovarian cancer risk. While the majority find a modest increase in risk, most lack statistical significance. The strongest association is seen in endometrioid histologies, where relative risks range from 1.2 to 5.5 (73).

Several retrospective and prospective studies have examined associations between dietary factors and ovarian cancer risk. Modest levels of protection have been reported for fruits and vegetables in general, and for vitamin A and β -carotene in particular, although findings are inconsistent (74,75). While there is some case-control data that invasive ovarian cancer is reduced among women who report frequent high-intensity exercise, the relationship between physical activity and ovarian cancer risk is inconsistent, and may differ by histologic type (65,76,77).

Chemoprevention

The majority of theoretical models of ovarian cancer chemoprevention have been based on the assumption that the origin of ovarian cancer is the OSE. As the paradigm has shifted to identifying the epithelial surface of the fallopian tube as the site of origin, it is not clear how to interpret the previous theories. Prior research has explored the presence of receptors for most members of the steroid hormone superfamily, including receptors for progestins, retinoids, androgens, and vitamin D. Progestins, retinoids, and vitamin D have been shown to exert a broad range of common biologic effects in epithelial cells, including induction of apoptosis, upregulation of transforming growth factor- β (TGF- β), cellular differentiation, and inhibition of proliferation. In addition to hormonal agents, there is growing evidence that nonsteroidal anti-inflammatory drugs (NSAIDs) may have ovarian cancer preventive effects (78). *It is yet to be demonstrated that these agents are active in the fallopian tube epithelium.*

To date, only OCP use has been consistently shown to be protective against ovarian cancer. OCPs were first introduced in the United States in the 1960s. Most formulations include estrogen, progesterone, or a combination of the 2. In addition to suppressing ovulation, OCPs also reduce pituitary secretion of

gonadotropins and protect against chronic inflammation associated with pelvic inflammatory disease (79). In addition to these potential mechanisms, a 3-year study on primates demonstrated that the progestin component of an OCP had a potent effect on apoptotic and TGF- β signaling pathways in the ovarian epithelium, raising the possibility that progestin-mediated biologic effects may underlie the protective effects of OCPs (80). The use of OCPs appears to decrease a woman's risk for ovarian cancer by 30% to 60%. Risk reduction is apparent with as little as 3 months of use, increases in magnitude with increased duration of use, and persists for as long as 10 years after discontinuation of use. The risk reduction applies to nulliparous as well as parous women, to all histologic subtypes, including tumors of low malignant potential, to women with a hereditary risk for ovarian cancer, is consistent across races, and is independent of age at use or menopausal status (70,81,82). Although there has never been a randomized clinical trial to demonstrate the protective effect of OCPs on ovarian cancer risk, it is often recommended empirically to women with a family history of ovarian cancer to reduce their risk.

Epidemiologic and laboratory evidence suggest a potential role for retinoids as preventive agents for ovarian cancer (83). Retinoids are natural and synthetic derivatives of vitamin A. They have great potential for cancer prevention, due to a broad range of important biologic effects on epithelial cells, including inhibition of cellular proliferation, induction of cellular differentiation, induction of apoptosis, cytostatic activity, and induction of TGF- β . The most significant evidence supporting a rationale for retinoids as chemopreventive agents for ovarian cancer is that of a chemoprevention study in Italy, which suggested an ovarian cancer preventive effect from the retinoid 4-HPR. Among women randomized to receive either 4-HPR or placebo in a trial designed to evaluate 4-HPR as a chemopreventive for breast carcinoma, significantly fewer ovarian cancer cases were noted in the 4-HPR group as compared to controls (84).

Vitamin D is a fat-soluble vitamin that is essential as a positive regulator of calcium homeostasis. The vitamin D receptor and the retinoic acid receptors share strong homology and readily dimerize, making it likely that vitamin D and retinoids have common signaling pathways in the cell (85). Vitamin D has been shown to have diverse biologic effects in epithelial cells relevant to cancer prevention, including retardation of growth, induction of cellular differentiation, induction of apoptosis and upregulation of TGF- β (86). With regard to ovarian cancer, a recent study has correlated population-based data regarding ovarian cancer mortality in large cities across the United States with geographically based long-term sunlight data reported by the National Oceanic and Atmospheric Administration. The study demonstrated a statistically significant inverse correlation between regional sunlight exposure and ovarian mortality risk suggesting that sunlight induces production of native vitamin D in the skin (87). However, a systematic review of 20 ecologic and case-control studies failed to find consistent evidence for a relationship between vitamin D exposure and ovarian cancer incidence or mortality (88).

Epidemiologic studies have suggested that use of NSAIDs may lower ovarian cancer risk (89). Several biologic mechanisms have been proposed to account for the chemopreventive effects of NSAIDs, including inhibition of ovulation, inhibition of COX, and downregulation of prostaglandins, enhancement of the immune response, and induction of apoptosis (70,90,91). Similarly, dietary antioxidants have shown an inverse association with ovarian cancer (92). Despite a growing body of preclinical data indicating chemopreventive effects of several agents, clinical research exploring their efficacy to reduce rates of ovarian cancer is hindered by the relatively low incidence of the disease, insufficient understanding of the preclinical course of ovarian cancer, the lack of validated preclinical biomarkers, and inadequate screening strategies.

Surgical Prophylaxis

For women with a family history of ovarian cancer, or a hereditary pattern of breast cancer, bilateral salpingo-oophorectomy (BSO) has been shown to lower the risk of subsequent epithelial ovarian cancer by 80% to 95% (66,93). Prospective follow-up of a large international cohort of 2,482 *BRCA* carriers found not only a lower risk of ovarian cancer, but also a significantly lower all-cause mortality (HR 0.40; 95% CI, 0.26–0.61) and ovarian cancer specific mortality (HR 0.21; 95% CI, 0.06–0.76). There is also a 50% reduction in rates of breast cancer in women who undergo prophylactic BSO (94). Occult invasive and *in situ* tumors have been found at the time of BSO in 2% to 10% of *BRCA1/2* mutation carriers (95), a large proportion of which occur in the fimbrial end of the fallopian tube (79,96), emphasizing the need for both deliberate removal of the fallopian tubes at the time of prophylactic surgery, and of careful pathologic examination of the surgical specimen (97). The incidence of primary peritoneal cancer following BSO is reported to be approximately 2% to 5% (98). Because the median age of diagnosis of ovarian cancer among women with a hereditary risk is 50 years, the recommended age for prophylactic surgery is at the completion of childbearing, or at age 35 to 40 years. Although the incidence of premenopausal ovarian cancer is higher in *BRCA1* carriers than *BRCA2* carriers, removal of the ovaries before menopause is recommended for both groups given the added benefit of breast cancer risk reduction, which is highest for women who undergo the surgery before natural menopause (17). In addition, because there is an approximate 15% risk of ovarian cancer after age 60 years among *BRCA* carriers, BSO is also justified at older ages for women who still have intact ovaries (99).

Women undergoing prophylactic hysterectomy for a deleterious mutation related to Lynch syndrome are also counseled to remove their ovaries because of the approximate 10% to 12% incidence of ovarian cancer (100).

In addition to the significant reduction in ovarian cancer incidence associated with BSO, several studies have found a significant decline in ovarian cancer worry and anxiety following the procedure (101). These potential benefits of prophylactic oophorectomy must, however, be weighed against its adverse consequences, including the short- and long-term surgical risks, the physical and psychological impact of early menopause, and the potential subsequent risks of cardiovascular disease and osteoporosis related to early estrogen/progesterone depletion (102). Although the use of combined estrogen/progesterone HRT has been associated with an increased risk for breast cancer among postmenopausal women in the general population, one study with short follow-up found no increased risk of breast cancer among *BRCA1/2* mutation carriers who took HRT following BSO (11). Also, data from the Mayo Clinic showed that there was no increase in breast cancer among women under the age of 50 years undergoing BSO (103). Women seeking information regarding prophylactic oophorectomy should be counseled about the practical short- and long-term sequelae of the surgery, the risks and benefits of postoperative HRT, and the small potential for primary peritoneal cancer.

Given the recent evidence that a majority of ovarian cancers arise in the fimbrial end of the fallopian tube, an alternative surgical procedure, radical fimbriectomy, has been introduced. The principle is that complete removal of both fallopian tubes will remove the source of the premalignant changes in the fallopian tube, which give rise to serous ovarian cancer. In addition, removing the tubes will prevent any endometrial tissue from reaching the ovary or peritoneal cavity. Because prospective data to establish the efficacy of this approach are lacking, and because there is still a proportion of ovarian cancer that may arise out of inclusion cysts in the ovary, radical fimbriectomy is currently proposed as a temporary solution which will prolong the production of ovarian hormone for *BRCA1/2* carriers, thus postponing the onset of premature menopause (104,105).

Table 6.3 Ovarian Cancer—Major Points

Several risk factors, including age, nulliparity, and family history, have been identified for ovarian cancer

Germ-line mutations in the *BRCA1/2* genes and the DNA mismatch repair genes associated with Lynch syndrome significantly increase the risk of ovarian cancer

Primary cancer of the fallopian tube is considered a component of the hereditary ovarian cancer syndromes

The fimbrial end of the fallopian tube, not the ovarian surface epithelium, has been identified as the source of most serous ovarian cancers

OCPs confer significant protection from ovarian cancer and the level of protection is related to the duration of use

Tubal ligation also confers significant protection from ovarian cancer, although the physiologic mechanism is unknown

Prophylactic bilateral salpingo-oophorectomy is the most effective method of preventing ovarian cancer in women with a hereditary pattern of ovarian cancer

Radical fimbriectomy has been proposed as a temporary alternative to bilateral salpingo-oophorectomy to forestall surgical menopause

No effective method of screening for ovarian cancer has been identified

OCPs, oral contraceptives.

Tubal ligation has been associated with lower ovarian cancer risk in both case-control and cohort studies. A strong inverse association was observed between tubal ligation and ovarian cancer risk in the Nurses Health Study, with a relative risk (RR) of 0.33 (CI, 0.16–0.64) after controlling for age, OCP use, and parity (106). A recent meta-analysis of 13 case-control, retrospective, and prospective studies found that tubal ligation reduced the risk of invasive epithelial ovarian cancer by 34% (RR 0.66; 95% CI, 0.60–0.73) (107). The International *BRCA1/2* Carrier Cohort Study found a 52% reduction in ovarian cancer among *BRCA1* carriers who had undergone tubal ligation (82). Proposed mechanisms include changes in local or circulating hormones, reduced access of carcinogens to the ovary, or a reduction in inflammatory processes. As it appears that a significant proportion of ovarian cancers arise in the fallopian tube, tubal ligation may reduce the risk by compromising the blood supply to the fimbrial end of the fallopian tube. Although the protective effect of tubal ligation appears to be substantial, the ability to perform BSO using a laparoscopic approach would seem to make this procedure a preferable choice among women with an increased risk of ovarian cancer (Tables 6.3 and 6.4).

Because of the risk reduction associated with BSO among high-risk women, some have advocated the routine removal

Table 6.4 Ovarian Cancer—Remaining Questions

What is the duration of latent, preclinical ovarian cancer?

What is the percentage of high-grade serous ovarian cancers that arise in the fallopian tube?

Can effective screening strategies, using biomarkers and/or imaging studies, be identified?

Are there effective chemopreventive agents that will reduce the risk of ovarian cancer?

What degree of protection from ovarian cancer does radical fimbriectomy confer?

of the ovaries among all women undergoing hysterectomy for benign conditions. However, data do not support the removal of the ovaries at the time of hysterectomy for benign disease in women at average risk of ovarian cancer, among whom the negative cardiovascular and metabolic impact of early surgical menopause outweighs any potential benefit (108,109).

ENDOMETRIAL CANCER

Risk Factors

Endometrial cancer is the most common gynecologic cancer in the United States. Over 45,000 new cases are diagnosed each year, and there are 8,100 deaths annually (16). Unlike many other tumors, the incidence and mortality from endometrial cancer is increasing, with a lifetime risk of 3% and a 16% risk of death (110,111). The increasing incidence of endometrial cancer is thought by some to be related to the increased prevalence of obesity (112). Worldwide, there are 287,900 estimated new cases per year (113). The relatively low case fatality rate is due to early detection and treatment of early-stage disease. The majority of risk factors associated with type 1 (endometrioid) endometrial cancer, viz. increased age, nulliparity, early age at menarche, late age at menopause, obesity, long-term use of unopposed estrogen replacement therapy, polycystic ovary syndrome (PCOS), and the use of tamoxifen, are all thought to exert their effect through estrogen-induced endometrial proliferation leading to hyperplasia and malignant transformation. The increased risk associated with diabetes, hypertension, and thyroid disease also suggests a role for altered growth hormone pathways in addition to the steroid hormone pathways (Fig. 6.8). There are also genetic syndromes associated with endometrial cancer. Women with germ-line mutations in the DNA repair genes associated with the HNPCC or Lynch syndrome

have a 40% to 60% risk of endometrial cancer. The mean age at diagnosis in this group is approximately 50 years (67). Epigenetic silencing of the Lynch syndrome genes by hypermethylation is also thought to contribute to endometrial cancer risk (114). Endometrial cancer is also a component of Cowden syndrome, in which it is estimated that mutations in the PTEN gene confer a lifetime risk for endometrial cancer of approximately 6%, with most cases occurring between the ages of 38 and 59 years (115). Type 2 serous endometrial cancer is uncommon and is not related to unopposed estrogen exposure.

Prevention

Risk Avoidance and Uptake of Protective Behaviors

It has been estimated that approximately 40% of endometrial cancers are attributable to excess body weight in developed countries (112) (Fig. 6.9). Maintenance of ideal body weight, regular physical activity, and control of diseases associated with endometrial cancer (diabetes, hypertension, and thyroid disease) are prudent approaches to reduce disease risk. Vigorous physical activity helps to control, prevent, or reverse weight gain, improve insulin sensitivity and reduce circulating estrogen levels, thus leading to a 22% reduction in endometrial cancer (116). Tamoxifen is a proven chemotherapeutic strategy to reduce the incidence of breast cancer in women at increased risk. While acting as an estrogen antagonist in the glandular epithelium of the breast, tamoxifen acts as an agonist in the endometrium, increasing the risk of postmenopausal bleeding, endometrial hyperplasia, endometrial polyps, and endometrial cancer. Although the absolute numbers were small, the relative risks for endometrial cancer in the National Surgical Adjuvant Breast and Bowel Project (NSABP) Breast Cancer Prevention Trial (BCPT) for women on the tamoxifen arm compared to placebo were

FIGURE 6.8. Molecular pathways involved in obesity and endometrial cancer.

FIGURE 6.9. Relative risk of death among US women by BMI.

2.53 (95% CI, 1.35–4.97) for all women, and 4.01 (95% CI, 1.70–10.90) for women aged 50 years and older (117). Women considering the use of tamoxifen for breast cancer risk reduction should carefully weigh the greater than two-fold risk of endometrial cancer with the benefits as they make their decision (118).

Chemoprevention

The addition of a progestin to the estrogen component of HRT has been shown to eliminate the increased risk of endometrial cancer. Progesterone controls many pathways resulting in growth inhibition and tissue homeostasis, and reverses the estrogen effect on the endometrium, thus preventing the development of hyperplasia. The use of combined estrogen and progesterone OCP decreases the risk of endometrial cancer by 50%, although their effectiveness in obese women is not clear (119). Oral progestins have long been used to reverse premalignant hyperplasia and to prevent the development of endometrial carcinoma (111). More recently, progestin-releasing intrauterine devices (IUDs), which deliver local therapy to the endometrium and spare some of the systemic effects, have been studied as an alternative to oral progestins both for women with early-stage endometrial cancer who desire to preserve fertility, and among those taking adjuvant tamoxifen following breast cancer treatment (115,120).

Surgical Prophylaxis

It is thought that the majority of invasive endometrial cancers progress through a series of premalignant stages, simple hyperplasia, complex hyperplasia, simple atypical hyperplasia, and complex atypical hyperplasia, all of which may present with abnormal vaginal bleeding (121). Conservative management of these conditions involves the use of progestational agents, which results in a complete regression of atypical hyperplasia in 50% to 94% of cases. Even in complete responders, however, there is a high rate of recurrence, and definitive therapy of atypical hyperplasia is hysterectomy (53). Among women with documented germ-line mutations associated with the Lynch syndrome, a retrospective study found that prophylactic hysterectomy conferred 100% protection from subsequent endometrial cancer (122). Because of the high success rate for endometrial cancer treatment,

Table 6.5 Endometrial Cancer—Major Points

The major risk factors for type 1 endometrial cancer exert their effect through estrogen stimulation of the endometrial surface epithelium.

Altered growth hormone pathways may also be involved in endometrial carcinogenesis.

Hereditary forms of endometrial cancer have been associated with the Lynch syndrome and with Cowden syndrome.

The majority of endometrial cancers present at an early stage with abnormal uterine bleeding.

Endometrial cancer screening is not recommended for the general population, although women with a hereditary risk are recommended to undergo annual endometrial biopsy.

Prophylactic hysterectomy in high-risk women has been shown to protect women from subsequent endometrial cancer.

however, it is not clear if this protection would translate into a significant survival benefit. This study also found 100% protection from ovarian cancer, which may warrant the consideration of prophylactic total abdominal hysterectomy–bilateral salpingo-oophorectomy (TAH-BSO) in this population. Alternatively, routine endometrial biopsies starting at age 30 to 35 years may be suggested in women with Lynch syndrome to detect early, premalignant endometrial lesions (123) (Tables 6.5 and 6.6).

Table 6.6 Endometrial Cancer—Remaining Questions

Can interventions targeting weight control and physical activity impact the incidence of endometrial cancer?

What are the most effective forms of progesterone-containing contraceptive preparations for reducing the incidence of endometrial cancer?

Does prophylactic hysterectomy translate into a survival benefit?

FUTURE DIRECTIONS

The prevention of gynecologic malignancies involves many disciplines and requires the collaboration of basic scientists, clinicians, behavioral scientists, and policy makers. The successful development of the HPV vaccines is a major breakthrough in the prevention of cervical cancer and will likely

undergo further improvements and refinements. Advances in molecular genetics, molecular pathology, and molecular imaging will contribute to the early identification of specific markers of premalignant change associated with gynecologic malignancies. The identification of safe and effective chemopreventive agents will provide additional strategies for prevention. Accompanying this progress will be the need to address the psychosocial and cultural barriers to the adoption of preventive strategies.

Preinvasive Disease of the Lower Genital Tract

BRITT K. ERICKSON ■ KENNETH H. KIM ■ MARK H. EINSTEIN ■
WARNER K. HUH

INTRODUCTION

At the forefront of any discussion on preinvasive and invasive lesions of the lower genital tract is the Human Papillomavirus (HPV). Infection with HPV is necessary for the development of almost all preinvasive cervical and vaginal lesions, and it is present in roughly half of preinvasive vulvar disease. Moreover, HPV is the most commonly diagnosed sexually transmitted infection in the United States with an overall lifetime prevalence of nearly 80% and a point prevalence of over 40% (1,2). Our knowledge surrounding HPV biology and epidemiology has increased exponentially in the past three decades, leading to improved screening modalities and recommendations as well as development of prophylactic vaccinations.

In this chapter, we will discuss the biology and epidemiology of HPV infections as they relate to cervical, vaginal, and vulvar carcinogenesis. Additionally, we will review clinical and HPV-associated risk factors for development of disease, the pathology of preinvasive lesions including cytology and histology, and discuss efficacy and impact of prophylactic HPV vaccination.

SECTION 1: HPV

Evidence for Causal Relationship

HPV was first proposed as a causative agent in the development of cervical cancer in the 1970s when Dr. Harald zur Hausen, a German physician and virologist, suggested that the same viral particles noted in genital warts may also be responsible for genital tract malignancies (3). This served to contrast the prevailing medical idea at that time that it was likely a herpes simplex virus that might have been the causative agent in cervical neoplasia. His work evolved and eventually in 1983, he isolated HPV type 16 and implicated its role in the development of cervical cancer (4). One year later, he had isolated HPV 18, thus discovering the two HPV types that today are associated with approximately 70% of all cervical cancers worldwide (5). For this body of important work, zur Hausen was awarded the 2008 Nobel Prize in Medicine.

In 1991, the International Agency for Research on Cancer (IARC) and the World Health Organization (WHO) concluded that, beyond a reasonable doubt, there is an association between HPV and cervical cancer (6). Though factors such as tobacco use, parity, contraceptive use, and sexual history may increase one's risk for development of the disease, persistent high-risk HPV infection is indisputably the most important causative factor (7). The association between HPV and cervical cancer is far higher than the association between smoking and lung cancer (8).

In fact, all steps, from HPV infection to cervical precancerous lesions, and from cervical carcinoma *in situ* to cancer, have been demonstrated in prospectively followed cohorts (9–11).

Classification of HPV

Papillomaviruses are double stranded DNA viruses that are members of the Alpha genus of the family Papovaviridae. Papillomaviruses are highly species specific and infect a wide range of vertebrate hosts. All papillomaviruses have regulatory, early (E) and late (L) genomic regions. Within a given host species, many types of papillomaviruses exist and this phylogenetic subdivision is determined by the extent of DNA relatedness. Specifically, the E6, E7, and L1 gene sequences must differ from one another by more than 10% to be classified as a distinct type, 2% to 10% to be a subtype, and 2% to be a variant of a subtype.

HPVs are epitheliotropic- infecting epithelial cells of the skin and mucous membranes and causing epithelial proliferation at the site of infection. HPV is currently divided into 120 distinct genotypes, and this list continues to expand (Fig. 7.1) (12). Over 40 types of HPV infect the anogenital tract (13). Traditionally, specific HPV types have been classified as high-risk types based on their potential to cause preinvasive and invasive disease. The most recent meeting of the IARC described 12 α -1 HPV types as high risk. These include HPV 16, 18, 31, 33, 35, 39, 45, 51, 52, 56, 58, and 59. Additionally, HPV 68, in the group α -2A, is categorized as probably carcinogenic (14).

Biology of HPV

HPV is a nonenveloped virus with a proteinaceous coat, which encases and protects the viral DNA. More specifically, the particle is composed of 72 capsomeres made of the viral proteins L1 and L2, also known as the major and minor capsid proteins, respectively. In addition to providing protection for the viral nucleic acid, the capsomeres also serve as the initial interaction site of the viral particle with the host cell.

The HPV genome is circular, double stranded, and contains nearly 8,000 base pairs (Fig. 7.2). The overall organization of various HPV types is similar. The genome contains eight open reading frames, which are transcribed as a single polycistronic mRNA and through alternative splicing mechanisms and ribosomal scanning, this mRNA is translated into the eight proteins E1, E2, E4, E5, E6, E7, L1, and L2.

The HPV genome can be divided into three regions. The first region is the upstream regulatory region (URR), composed of nearly 1,000 base pairs. The URR does not code for proteins but contains binding sites for different cellular transcriptional activators and repressors, which then regulate the expression of the early viral genes (15). This region also contains binding sites

FIGURE 7.1. Papillomavirus phylogenetic tree.

for the viral proteins E1 and E2, which initiate viral replication and transcription (16). The URR is necessary for the regulation of gene expression, replication of the genome and packaging of virus particles.

The URR primarily regulates the transcription of proteins in early infection including proteins E6, E7, E1, and E2. The late promoter is activated during the productive phase of the viral life cycle and results in transcription of the capsid proteins (L1 and L2) as well as E1, E2, E4, and E5.

HPV Lifecycle

Like other viruses, HPV must deliver its genome to the host cell and subsequently exploit the cellular machinery for its own purposes. HPV infects the host at sites of epithelial microtrauma, where the HPV particle can gain access to the actively proliferating basal cells of the epithelium (Fig. 7.3). The mechanisms of cell entry are complex and continue to be better elucidated (17). The HPV particle interacts with the cell surface via its major and minor capsid proteins (L1 and L2). α -6-Integrin had initially been suggested as a receptor; however, controversies exist regarding its specific involvement with HPV (18,19). Attachment receptors for HPV particles are likely heparan sulfate proteoglycans

(HSPG), specifically syndecan-1, which is found in the extracellular matrix of epithelial cells (19). Laminin-5 may be another specific extra-cellular matrix receptor involved in binding and cell entry (20,21). Though the main target of HPV are the keratinocytes of the epithelium, HPV virus-like particles have also been shown to attach to cells important in immune function such as dendritic cells and Langerhans cells (22).

The binding of HPV to cell surface receptors in the basal cells over the basement membrane then initiates conformational changes in L2, which exposes additional binding sites (23,24). HPV then enters the cells via endocytosis. Most studies suggest clathrin or caveolin-dependent endocytosis (25), although internalization independent of these proteins has also been described (26).

Once inside the basal epithelial cells, the viral genome begins to replicate and maintains about 50 to 100 copies per cell. The life cycle of HPV is closely linked to the state of differentiation of the squamous epithelium of the natural host tissue. In normal squamous human epithelium, the basal layers (stratum basale) are the areas of active cell division. After division, the daughter cells migrate away from the basal cells (stratum spinosum) and no longer progress through the cell cycle. Instead, these terminally differentiated cells produce high-molecular-weight keratins until eventually the nuclear envelope breaks down and the cells become empty keratin-filled sacs (stratum corneum).

FIGURE 7.2. Schematic of genomic organization of HPV.

Source: Reprinted with permission from Wright TC, Ferency AF, Kurman RJ. Precancerous lesions of the cervix. In: Kurman RJ, ed. *Blaustein's Pathology of the Female Genital Tract*. 4th ed. New York, NY: Springer-Verlag; 1994:229–241.

When the HPV-infected basal cell divides, the viral DNA segregates with the 2 daughter cells, 1 cell remains as part of the basal epithelium while the other migrates to the next layer. Because terminally differentiated cells of the upper epithelial layer contain little or no enzymes, in order to replicate, the virus causes the cell to reenter S phase, causing only partial instead of terminal differentiation. Thus the viral genome replication is synchronous with the cellular DNA replication. HPV infected cells migrate away from the basal layer and as

the cells reach higher epithelial layers the late promoter is activated and late gene transcription and translation occur. There is high-level amplification of the viral genome in these layers and in the uppermost layer, DNA is packaged into capsids and the infectious virions are assembled. Typical HPV-associated cytopathic changes such as koilocytosis, multinucleation, and nuclear enlargement are due to the assembly of the viral particles in the upper epithelial layers. The epithelium is then shed and HPV particles are released, which can then infect a new host.

Oncogenic Proteins

The oncogenic potential of high-risk HPV is primarily attributed to the E6 and E7 proteins. E6 and E7 proteins differ in high-risk and low-risk types. These proteins do not have intrinsic enzymatic activities, but instead interact directly and indirectly with other cellular proteins affecting cell cycle regulation. In addition to their individual effects, their combined effects are likely synergistic. In transgenic mouse models, the combinations of E6 and E7 have resulted in particularly aggressive invasive cancers (27).

HPV E7

The E7 protein is responsible for immortalizing cells infected with HPV, primarily by affecting the cell's transition from G1 into S-phase. E7 has a variety of targets including the retinoblastoma (Rb) protein family, histone deacetylases, cyclins, cyclin-dependent kinases (cdks) and cdk inhibitors (28). E7 is composed of 98 amino acids and is divided into 3 domains. CR1 is the amino terminus consisting of amino acids 1 to 20. The CR2 domain (amino acids 21 to 39) contains a sequence that binds E7 to retinoblastoma tumor-suppressor proteins. The CR3 domain (amino acids 40 to 98) contains zinc finger motifs that are essential for protein folding (29).

Rb proteins regulate the cell cycle by controlling the transition at the G1/S phase. Rb is hypophosphorylated and bound to E2F, a cellular transcription factor. In its bound state, Rb and

FIGURE 7.3. Diagram of normal epithelium and HPV-infected epithelium.

Source: Reprinted with permission from Hebner CM, Laimins LA. Human papillomaviruses: basic mechanisms of pathogenesis and oncogenicity. *Rev Med Virol* 2006; 16(2):83–97.

E2F inhibit cellular proliferation. In normal cells, when cyclin-kinase complexes phosphorylate Rb, E2F is released and transcription of S phase genes occurs. E7 disrupts this process. The CR1 and CR2 domains of E7 bind to and degrade hypophosphorylated Rb, disrupting the Rb-E2F complex (30,31). E2F is released, which results in the expression of S-phase genes.

The zinc finger region of E7 can interact with the class I histone deacetylases (HDACs). Through deacetylation of histones, HDACs induce chromatin remodeling (32). E7 binding to HDACs causes progression into S-phase thereby lengthening the life of the cell.

Independent of these effects, continuous activity of the E7 protein leads to increasing genomic instability, which leads to more dysregulated cell growth and eventually cancer. It has been observed that cells expressing E7 show irregularities in numerous centrosomes leading to aberrant mitotic spindle poles, thereby affecting chromosome number during replication (33). E7 expression is a late event in malignant transformation.

HPV E6

Like E7, E6 is a small 151 amino acid protein that induces important changes in the host cell. It also lacks endogenous enzymatic activity and binds to cell cycle-regulatory proteins, affecting life cycle and immortalization.

E6's most notable effect is its ability to bind to p53. p53 is a transcriptional activator and is an important tumor-suppressor gene. p53 induces expression of genes involved in apoptosis and cell cycle arrest. p53 levels typically increase in response to stress, DNA damage, or abnormal cellular proliferation (e.g., radiation exposure, hypoxia, and infection). This increase in p53 corresponds to arrest in the G1 phase of the cell cycle, thereby allowing for repair of DNA damage or progression to apoptosis. In HPV infected cells, E6 binds to p53 and causes degradation of the protein through a ubiquitin-dependent pathway. Thus less apoptosis and growth-arrest occurs, leading to cellular proliferation (34).

E6 has also been shown to interact with other proteins that are involved in a variety of cellular functions. E6 binds to transcriptional co-activators CBP/p300, further downregulating p53-mediated transcription (35). E6 also interacts with the PDZ proteins, which are involved in cell signaling and cell-to-cell adhesions, which ultimately affects lifecycle and carcinogenesis (36–38).

In addition to its inhibition of apoptosis through p53 interaction, E6 also upregulates the cellular telomerase complex. By synthesizing new DNA, telomerase maintains the length of the telomeric DNA at each end of a chromosome. Without this, the telomeres shorten with each cell division until they reach a critically short length and can no longer replicate. Therefore, by up-regulating the cellular telomerase complex, E6 further immortalizes the host cell (39,40). E6 expression is a late event in malignant transformation.

HPV E1/E2

Both E1 and E2 are proteins necessary for HPV DNA replication. E1 first initiates viral replication by binding near the start site of transcription. E1 complexes with the E2 protein, then binds to the viral genome, which initiates helicase activity (41). E1 also binds various other nuclear proteins for further replication of the viral DNA (42–44).

E2 is involved with DNA replication as well as genome transcription. In addition to forming a complex with E1 to assist in replication, E2 also works on the upper regulatory region to affect transcription of early genes (45,46). High concentrations of E2 repress transcription and low levels activate transcription.

E2 therefore regulates E6 and E7 and loss of E2 expression can lead to carcinoma due to the unrestricted effects of E6 and E7 (47). Like E1, other interactions have been noted between E2 and various proteins involved with transcription as well as mitosis and cell division. E1 and E2 expressions are early events in the natural history of cervical dysplasia.

Viral Integration and Transformation to Malignancy

HPV genomes infect the cell via circular extra-chromosomal copies; however, over time, its viral genome can become inserted into host cell DNA, a process called integration. In low-grade cervical intraepithelial neoplasia (CIN), the HPV DNA is maintained in its closed, circular, episomal shape. However, in most high-grade CIN and cancers, the HPV DNA becomes integrated in the host chromosomal DNA (47–50). Many believe this is a necessary event to cervical carcinogenesis (51). Integrated HPV has been found to be present in 83% of invasive cervical cancers, as compared to 8% of low-grade CIN, suggesting that integration is highly associated with the transition of low-grade to high-grade lesions (52,53). Integration occurs at random sites in the host DNA; however, breaks in the HPV viral episome seem to occur at regions of genomic instability, such as fragile sites. Often the E2 ORF is disrupted during these breaks (54). As noted previously, E2 concentration affects the transcription of E6 and E7. Thus, once integration has occurred, disruptions in the E2 ORF lead to increased production of E6 and E7, thereby promoting immortalization and the oncogenic potential of the cell.

SECTION 2: EPIDEMIOLOGY OF HPV INFECTIONS

Prevalence

HPV is the most common of all sexually transmitted infections; while age, race, geographic region, and other modifiable risk factors also correlate with new infections, age, and sexual behaviors are most clearly linked to new HPV infections. Early studies likely underestimated the prevalence of HPV infections. As newer molecular technologies have been developed, detection of viral infection improved, even at low levels (55). In addition to variability surrounding detection methods, HPV positivity may be episodic, corresponding to times of viral shedding.

Utilizing polymerase chain reactions (PCR) on self-collected cervicovaginal specimens from over 4,000 US females, ages 14 to 49, the prevalence of HPV infection was recently estimated as part of the 2011 National Health and Nutrition Examination Survey (NHANES) (1) (Fig. 7.4). The overall prevalence of the 37 separate types was 42.5%. Prevalence was lower among females aged 14 to 19 (32.9%) and highest among females 20 to 24 years (53.8%), which is the peak age of new exposures. In that study, prevalence varied by race with non-Hispanic Blacks having the highest prevalence (59.2%) followed by Mexican Americans (44.2%) and non-Hispanic Whites (39.2%). HPV positivity was significantly associated with poverty, sexual activity (including number of partners, age, and first encounter) and history of genital warts.

HPV Prevalence Worldwide

Worldwide age-related trends are similar to US cohorts (56). Women less than 25 years old showed the highest prevalence of HPV infection, and in most regions of the world showed an

FIGURE 7.4. U.S. Prevalence of HPV infections in Women.

Source: Reprinted with permission from Hariri S, Unger ER, Sternberg M, et al. Prevalence of genital human papillomavirus among females in the United States, the National Health And Nutrition Examination Survey, 2003–2006. *J Infect Dis* 2011;204:566–573.

overall decrease in prevalence with increase in age. In Africa, prevalence ranges from 12% to 55%, though most trials consisted of younger cohorts of women. In Central and South America, prevalence has been reported to be as high as 64%, and interestingly many studies showed an overall decrease in prevalence with age followed by an upward trend in women over 50. Canadian prevalence was lower than in the US, with a peak incidence of 25%. Chinese trials showed a range of 6% to 53% while Japanese trials generally reported lower prevalence of less than 15%. Studies of Indian women show ranges from 0% to 45%. European prevalence was almost consistently lower than in the United States with a peak of approximately 20% in young women (56).

HPV Prevalence in Men

The trends in prevalence and clearance in men are inextricably linked to the epidemiology of HPV infections in women. HPV testing in men has limited yield when compared to HPV testing in women, due to the generally keratinized surfaces where HPV-infection is present in men. The largest US population-based

FIGURE 7.5. HPV prevalence in US Men.

Source: Reprinted with permission from Giuliano AR, Lazcano-Ponce E, Villa LL, et al. The human papillomavirus infection in men study: human papillomavirus prevalence and type distribution among men residing in Brazil, Mexico, and the United States. *Cancer Epidemiol Biomarkers Prev* 2008;17:2036–2043.

trial investigating HPV infection in men, where sampling was thoroughly performed, demonstrated a prevalence of 61% of any type of HPV infection. Specifically, high-risk HPV infections were found in 23%, with HPV 16 (7%) and HPV 51 (6%) being the most common (57). Additional data from the NHANES survey showed that men have a higher incidence of oral HPV infection of 10% versus 4% (58). In contrast to trends in women, prevalence of any HPV infection was not affected by age. Only low-risk HPV infections increased with age. Clearance of HPV infections seems to occur quicker in men, with an average clearance time of any HPV infection of approximately 6 months. In one study, nearly 75% of HPV infections in men were cleared within 1 year (57). Male circumcision significantly reduces genital HPV prevalence in men, which has led some to suggest circumcision as a method to reduce HPV-related disease burden in endemic communities where vaccination and screening is not yet feasible (59). In contrast to squamous cell carcinomas (SCC) of the female genital tract, HPV has only been detected in half of invasive penile SCC (60).

Natural History of HPV Infection (Rates of Abnormal Cytology, CIN, Cancer)

Despite its high prevalence, the majority of HPV infections are cleared by the body's immune system. Only a minority of persistent high-risk HPV infections result in CIN and an even smaller subset progress to invasive cancer.

Determining the exact rate of HPV clearance is complex. Some trials examine existing infections (prevalence trials) while others follow women who develop new infections (incident trials). Even within incidence-based trials, methods vary and any subject may have a combination of low-risk, high-risk, preexisting, or incident HPV infections. It is important to also note that though a negative HPV test likely represents clearance of infection, it may also represent a “latent,” subclinical infection. This concept is derived from a number of sources including data examining HIV positive women who became HPV positive in the absence of new sexual exposures, suggesting a reactivation of viral shedding during periods of immunodeficiency (61). Also, in long-term cohort studies, recurrent infections are often HPV types that the patient has previously had, suggesting reactivation (62). However, once cleared, very few HPV type-specific infections reappear and far fewer lead to clinically relevant disease such as high-grade CIN or cervical cancer (63).

The 1-year clearance rate of incident HPV infection ranges from 40% to 70%. Two- to 5-clearance rates are as high as 70% to 100% in young women (10, 64–67). This rate may be significantly lower in older women; one trial showed no clearance of high-risk HPV infections in women over the age of 70 (67). Young women are more likely to clear infections than older women, and low-risk HPV infections clear more quickly than high-risk HPV infections (64). The longest course of persistent infection was seen with HPV types 16, 31, 54, and 53 (64,68).

The majority of women who acquire HPV infections do not develop CIN or invasive cancer. Of women who have persistent high-risk HPV infections, trials report variable rates of progression to CIN 2/3 from 8% to 28% (69–71). In cross-sectional studies, an estimated 3% to 5% will eventually develop cervical cancer without any intervention (72,73). In a prospective cohort study of New Zealand women with carcinoma *in situ* followed over decades, the cumulative incidence of cancer of the cervix or vaginal vault was over 30% (9).

Transmission

HPV infections are almost exclusively acquired during sexual exposure. Areas of microtrauma within the skin and mucosal surfaces are the likely sites of initial infection. Many natural history

studies of HPV negative women at baseline who initiated intercourse confirm precedent sexual activity with new HPV infections (10). Furthermore, the rate of acquisition correlates with increasing number of sexual partners (74). Data regarding concordance and HPV transmission efficacy among couples are conflicting. In trials of young women and their male partners, HPV concordance ranged from 40% to 60%. Specific mechanisms that determine the efficiency of HPV transmission and concordance are poorly understood although it appears that length of sexual activity may increase concordance (75–77). Additionally, viral shedding may occur based on asynchronous replicative cycles of the HPV virus; thus, couples may appear to be less concordant than they really are at any specific time (68). In addition to cervical, vaginal, and penile detection, HPV has been detected on areas of unprotected genital skin such as the vulva and scrotum, providing an explanation as to why condoms offer some but not complete protection against HPV infection (78).

SECTION 3: ADDITIONAL RISK FACTORS FOR DEVELOPMENT OF PREINVASIVE LESIONS OF THE LOWER GENITAL TRACT

Although HPV has been implicated as the most important and necessary risk factor for development of preinvasive lesions of the lower genital tract, other risk factors have been identified that either increase the risk of HPV infection or potentiate the progression of HPV infection to malignant transformation.

Sexual History

Even before data convincingly linked HPV to the development of cervical cancer, it was well recognized that various aspects of a patient's sexual history put women at increased risk for developing preinvasive and subsequent invasive lesions of the cervix, vagina, and vulva.

Sexual history and behaviors strongly correlates with risk of acquiring HPV infection and developing preinvasive lesions (66). Overall, the number of recent and total lifetime male partners increases the rate of HPV infection, particularly high-risk HPV infection (66,79–82). The most recent data from the U.S. Centers for Disease Control (CDC) data show that number of lifetime partners is an independent risk factor for all races except non-Hispanic Black women, where no independent correlation is seen (83).

Early onset of sexual activity has also been shown as an independent risk factor for HPV infection in some studies (81,83). Some studies suggest that frequency of intercourse with one's partner may also play a role (10). Characteristics of the

partner, including number of lifetime partners (79) and multiple coincidental partners, have all been implicated in risk of HPV acquisition (10). The rate of having new partners and having known a new partner for shorter periods of time before having vaginal intercourse are also associated with increased risk of HPV infection (66,79).

Additionally, co-infection with other sexually transmitted diseases and vaginal infections has been associated with increased susceptibility to HPV infection. Both bacterial vaginosis and trichomoniasis are associated with HPV infection although the correlation is not as strong with development of CIN (84,85). A history of herpes simplex virus infection and vulvar warts also increase the incidence HPV infection (66). A history of previous chlamydial infection has long been implicated in the development of invasive squamous cell carcinoma of the cervix (86–88). Hypotheses regarding pathogenesis include induction of squamous metaplasia at the transformation zone, increase in microabrasions, as well as interference with immune surveillance (88,89). More recent cohort studies have found that the role of chlamydia in carcinogenesis is likely related to both in promoting the acquisition and persistence of HPV infections (90–92). Chlamydia has not been implicated in the development of adenocarcinoma *in situ* (AIS) or invasive adenocarcinoma (88).

Tobacco

In 2004, the IARC added cervical cancer to the list of cancers causally related to smoking (93) based on analysis of numerous trials in the prior decade. As more epidemiologic and natural history trials were performed, conflicting data emerged on the association between cigarette smoking and HPV acquisition, persistence, and progression. Confounding variables have also been a factor; women who smoke are less likely to be compliant with screening guidelines (94) and more likely to have more social stressors (95).

Most studies agree, though, that current smoking increases the prevalence of and persistence of HPV infection, particularly those that have a high-risk HPV type (96–99). Additionally, most trials suggested delayed clearance of HPV infection in women who smoke (100,101). Compared to nonsmokers and former smokers, current smokers have higher high-risk HPV viral loads (102).

The effects of smoking on the development of lower genital tract neoplasia are multifactorial. Nicotine and other by-products of cigarette smoke have been readily identified in the cervical mucus of smokers (103). Benzo[a]pyrene, a known human carcinogen, has been found in cervical mucus and has been specifically noted to potentiate the HPV 16 and HPV 18 viral lifecycle (104). It has long been known that smoking causes a local immunological effect whereby the function of Langerhans' cells are significantly decreased, thus affecting the

innate immune system (105). Studies of women with preinvasive and invasive disease have shown that compared to nonsmokers, smokers show aberrant methylation of p16, a tumor suppressor gene (106). Other recently identified tumor markers in smokers with CIN include overexpression of cyclooxygenase-2 and Ki-67 and underexpression of p53, interleukin-10, and fragile histidine triad (107).

Oral Contraceptive Pills

The association between oral contraceptive pills (OCPs) on preinvasive and invasive diseases of the lower genital tract has been conflicting. The largest population-based study, which pooled data from trials involving over 50,000 women worldwide, did show an increased risk of preinvasive and invasive disease in women who were current users of OCPs, although this risk was eliminated when OCP use was discontinued (108). This study is criticized for its heterogeneity between trials and the possible confounding effects of sexual behavior in women on OCPs—thus, many have questioned the true association. Other large trials since then have shown that OCP use is not an independent risk factor for development of abnormal cytology, CIN, AIS, or invasive disease (109–111).

HIV and Immunosuppression

HIV infection is strongly associated with HPV infection. Additionally, HIV coinfection in one partner impacts the prevalence of HPV infection in the other partner (112). Higher incidence and prevalence as well as prolonged persistence of HPV have all been associated with women who are HIV positive (113). Rates of CIN are also higher among HIV positive women, independent of other risk factors (114). Additionally, CD4 count and HIV RNA levels correlate with high-risk HPV positivity (61). Although highly active antiretroviral therapy (HAART) has not been shown to definitively affect the incidence or persistence of HPV infections, it has been associated with better CIN outcomes and improves overall life expectancy of HIV positive women (115).

In addition to its effect on prevalence of HPV infection, other mechanisms related to coinfection of HPV and HIV have been proposed. Primarily, it is noted that a functional immune system is required to keep HPV in a latent and subclinical state. Thus HIV infection, in addition to other forms of immunosuppression, predisposes to progression and reactivation of HPV infection (61). Additionally, different molecular pathways have been proposed for HIV-related preinvasive lesions including a higher frequency of microsatellite instability in HIV associated CIN (116). Based on patterns of local pro-inflammatory immune markers, it appears that persistent HPV infection might make someone more susceptible to HIV infection as well.

Another group of women known to be at high risk for preinvasive HPV-associated lesions are transplant recipients and other patients on chronic immunosuppressive therapy such as those with Systemic Lupus Erythematosus. Small, early studies noted a higher incidence of HPV infections and up to 16 times the rate of invasive cervical cancer in women with a history of renal transplant compared with controls (117). However, these data are limited by less effective methods of HPV testing and lack of control for covariates. In a recent prospective 10-year trial of 48 women with renal transplants, no increased risk of HPV infection, high-grade cytology, or preinvasive lesions was observed (118). A large Swedish cohort study found that the rate of vulvar malignancy in women who had undergone solid organ transplant was 26 times higher than the general population. Additionally, the rate of vaginal cancer was 16 times higher. Rates of cervical cancer were not statistically higher and

preinvasive lesions were only marginally increased (119). A U.S. cohort of transplant recipients was analyzed and only vulvar carcinoma demonstrated a statistically significant higher incidence in transplant recipients. In fact, the incidence of vulvar carcinoma following a solid organ transplant was higher than the incidence of cervical cancer (7.5 vs. 5.8 per 100,000 person years) (120). This may reflect improved cervical cancer surveillance in this population. However, it may also reflect the different pathology of vulvar lesions in immunocompromised women. Smaller studies suggest rates of 90% to 100% HPV positivity in preinvasive and invasive vulvar lesions in women with transplants (121,122).

SECTION 4: PATHOLOGY OF PREINVASIVE LESIONS

Cervix

Formerly known as cervical dysplasia and carcinoma *in situ* (CIS), preinvasive squamous cell lesions of the cervix are now categorized as various levels of CIN. More specifically: mild, moderate, and severe dysplasia/CIS are now termed CIN 1, CIN 2, and CIN 3, respectively.

CIN Localization

The vast majority of CIN develops in the transformation zone of the cervix, located at the squamo-columnar junction between the columnar epithelium of the endocervix and the squamous epithelium of the ectocervix. This area has been so-called “transformed” due to the process of metaplasia (Fig. 7.6). Prior to menarche, the transformation zone does not exist. The squamo-columnar junction occurs exactly at the level of the external cervical os. During menarche (as well as during pregnancy), the columnar epithelium of the endocervix appears on the ecto-cervix and is termed an “ectropion” or “cervical ectopy.” This columnar epithelium gradually becomes replaced by stratified squamous epithelium due to a variety of factors including alterations in pH and other hormonal changes. This area of former columnar, now squamous, epithelium that lies between the original squamocolumnar junction and the new squamocolumnar junction is termed the transformation zone. The transformation zone is the primary site for inducing cell-mediated immunity in the lower genital tract, and its role in the acquisition of not only HPV infections, but also HIV infections is still being elucidated (123,124).

Microscopic Appearance of CIN

Nuclear atypia is a prominent feature of CIN, which can occur at any level of dysplastic severity. It occurs as a result of enhanced proliferation, replication, and intracellular assembly of viral particles in HPV infected cells. The nuclei are hyperchromatic and frequently multinucleated; additionally, the nuclear outline is often irregular rather than round. The swollen appearance of the cells, often termed as koilocytes, is a result of viral particles present in the episomal area of the cell.

In addition to nuclear atypia, CIN 1 to 3 histology shows aberrant cytoplasmic differentiation. The basaloid cells, which are normally found as a single layer in contact with the basement membrane, replace the normal epithelium. These cells display nuclear crowding, loss of normal cell polarity, pleomorphism, and abnormal mitotic figures. The extent of these abnormal basaloid cells determines the grade of CIN. If the undifferentiated basaloid cells involve the lower third of the epithelium, the lesion is CIN 1; if these cells are present two-thirds of the way

FIGURE 7.6. Impact of age on the location of the squamocolumnar junction. As females age, the location of the squamocolumnar junction on the cervix moves. The movement of the squamocolumnar junction defines the transformation zone.

through the epithelium, the lesion is CIN 2; and if the extent is greater than two-thirds, the lesion is termed CIN 3. In order to better classify the degree of CIN, molecular markers can be used by pathologists. For instance, p16^{INK4a} is a validated marker for biologically relevant CIN (125).

This classification system was developed when all of CIN was thought to be a spectrum of disease. Now we understand that CIN 1 usually represents a benign process that is merely a cytomorphologic representation of an active HPV infection; whereas higher-grade lesions, especially CIN 3, are truly premalignant. CIN 2 is a poorly reproducible category, with high levels of inter-observer variability (126). In one trial, agreement between pathologists was as low as 13% in the category of CIN 2 compared with 81% agreement with CIN 3 lesions (127). CIN 2 is now considered an equivocal diagnosis because it can include either benign HPV effects or precancerous lesions (125). In an analysis of a vaccine trial, agreement between biopsy and LEEP specimen improved when CIN 2 and CIN 3/AIS were grouped as a single predictive measure of high-grade disease (128). Due to limitations surrounding reproducibility, many institutions characterize lesions as either CIN 1 or CIN 2/3 (also known as CIN 2+); and often include additional molecular markers such as p16^{INK4a} and other proliferation markers to improve clinically relevant disease ascertainment (Fig. 7.7).

In CIN 1, the lower third of the epithelium displays nuclear atypia of immature basaloid cells while the remainder of the epithelium often shows the additional cytopathic effects, termed koilocytosis, which are directly related to an active HPV infection. Koilocytes are cells with atypical nuclei and perinuclear clearing, also known as vacuolization; they can be seen in both CIN 1 and CIN 2/3, although it is more common in CIN 1. The large, perinuclear vacuole is often a result of activation of viral E5 and E6 proteins (129).

Natural History of CIN

CIN 1 is the most common histologic diagnosis after colposcopic biopsy. Fortunately, very few of these lesions actually progress to a higher grade of CIN. Most will remain persistent or regress spontaneously as the HPV infection is cleared (130). In both prospective and retrospective trials, incidence of CIN 2/3 18 to 24 months after diagnosis of CIN 1 ranges from

4% to 10% (131,132). A retrospective analysis of the ASCUS-LSIL Triage Study (ALTS) (133) found that a diagnosis of CIN 1 on pathology (compared to a negative biopsy, or no biopsy taken) was not a risk factor for developing CIN 3. Therefore, CIN 1 is considered a nonneoplastic lesion and is not a disease that should require any extirpative treatment.

Without treatment, high-grade CIN has at least a 30% probability of becoming invasive cancer. This was shown in an unfortunate retrospective trial of a prospectively followed cohort of women followed over a 30-year period beginning in the 1960s in New Zealand. If adequately treated, however, very few women with CIN 2/3 will recur or develop invasive cancer (9).

Glandular Dysplasia and Adenocarcinoma In Situ

Although the majority of preinvasive cervical lesions are of squamous cell histology, approximately 3% represent precursors to invasive adenocarcinoma (134). While HPV 16 is the most commonly identified subtype in glandular lesions, HPV 18 causes a greater proportion of glandular as compared to squamous lesions (135). Contrary to popular conceptions regarding preinvasive glandular lesions, the majority are solitary. Multifocal (or “skip lesions”) do occur, but only in 10% to 15% of cases. Though glandular lesions can be found higher in the endocervical canal, the majority occur at the squamocolumnar junction (136).

Preinvasive glandular lesions can be divided into the categories of endocervical glandular dysplasia (EGD) and AIS. These categories differ by degree of nuclear stratification, nuclear atypia, and numbers of mitosis and apoptosis. Additionally, immunohistochemistry, such as staining for a proliferative marker, Ki-67, may also be used to help differentiate between the two categories (137). An additional category, termed glandular atypia, encompasses nonpremalignant lesions with atypia associated with inflammation or previous radiotherapy. Rare variants of AIS have been described including endometrioid, intestinal, serous, and clear cell histologies.

Histologically, AIS is characterized by enlarged glandular cells with large, hyperchromatic nuclei (Fig. 7.8). Unlike the cytopathic effect of koilocytosis seen in HPV infected squamous cells, endocervical cells show decreased cytoplasm and minimal intracellular mucin. Structurally, glandular cells are crowded

with pseudostratification. Unlike squamous lesions, apoptosis is a common feature in glandular lesions and is seen in higher frequency in AIS compared to invasive adenocarcinoma (138).

Diagnosing early invasive endocervical adenocarcinoma is sometimes more challenging than diagnosing squamous lesions due to the complex growth patterns of endocervical glands.

Atypical glands that extend greater than 5 mm from the uninvolved glands are usually termed invasive, whereas lesions within 5 mm are considered early invasive disease. Other features distinguish invasion from *in situ* lesions including stromal reaction (desmoplasia, inflammation), confluence of glands, and solid components.

Vulva

Vulvar intraepithelial neoplasia (VIN) is increasing in incidence in the United States, with a 400% increase in preinvasive lesions and a 20% increase in invasive lesions between 1973 and 2000 (139). Classification of preinvasive vulvar disease has undergone many changes. In 2003, the WHO classified VIN in a 3-grade system for all types, similar to preinvasive cervical disease. Then, in 2004, the International Society for the Study of Vulvovaginal Disease (ISSVD) reclassified VIN into 2 categories: usual-type VIN, which is associated with HPV infection; and differentiated VIN, which is usually not associated with HPV

infection (140). VIN 1 was abandoned in terminology primarily due to its high rate of misclassification into clinically relevant disease. Usual-type VIN includes only high-grade VIN and is composed of warty, basaloid, and mixed histologies. In addition to being an HPV-associated lesion, usual-type VIN shares the same risk factors as those for CIN including tobacco use and immunodeficiency. Differentiated VIN, sometimes referred to as “keratinizing type,” occurs most commonly in older women and is often associated with lichen sclerosis. p53 mutations and microsatellite instability have been implicated in its pathogenesis. Five percent of women with lichen sclerosis develop invasive squamous cell carcinoma with an average interval of 10 years (141). Differentiated VIN has a greater propensity to progress to invasive disease, and time to progression is shorter than that of usual-type VIN.

The differential diagnosis for vulvar lesions is broad and diverse. Distinguishing benign from preinvasive lesions can be difficult by visual inspection alone and thus biopsy is usually necessary to establish diagnosis. Usual-type VIN appears as a sharply demarcated lesion that can exhibit various colorations including white, gray, red, and black. VIN is most commonly found at the introitus, on the labia minora, and around the anus. When the disease spreads beyond the anal verge, it is referred to as anal intraepithelial neoplasia, or AIN, and lesions are frequently multifocal (142). Microscopically, VIN resembles CIN and displays nuclear atypia and cytoplasmic differentiation.

Natural History of VIN

Based on retrospective reviews, an estimated 10% to 15% of untreated VIN will progress to invasive squamous cell carcinoma over many years (143,144). Additionally, up to 20% of women with high-grade VIN will have occult invasive disease at the time of surgery for preinvasive disease (145). Unlike CIN, regression of VIN is rare; one review noted only a 1% complete regression of VIN 3 (144).

Vagina

Vaginal intraepithelial neoplasia (VAIN) is another lesion that is part of the HPV spectrum in the lower genital tract. Its occurrence is less common and represents only 0.5% of all lower genital tract intraepithelial neoplasias. VAIN is most often found in the upper vagina and is most often multifocal. Many cases occur after hysterectomy and occult vaginal malignancy is uncommon (146). Recurrence is more common with multifocal disease and ranges from 20% to 60% after treatment with laser or 5-fluorouracil (146,147). Recurrence is uncommon after partial vaginectomy (147). HPV infection is implicated in the pathogenesis of over half of VAIN (148). The histologic features of VAIN are similar to those of CIN and VIN. Due to its infrequency, there are no current recommendations for vaginal cancer screening. Most screening recommendations do not recommend performing vaginal cuff cytology after a hysterectomy (149).

SECTION 5: SCREENING

With the advent of successful screening for preinvasive disease of the lower genital tract, effective treatments of precancerous lesions has also emerged, subsequently affecting the overall disease burden of invasive lower genital tract malignancies.

Cervical cancer screening is hailed as one of the major public health advances in the 20th century. Initially seeking determinants of the ovulation cycle in guinea pigs, Dr. George Papanicolaou evaluated the vaginal smear as an indicator of

hormone status. Eventually he studied human subjects and incidentally found a malignancy on a vaginal smear. More than a decade later, Dr. Papanicolaou and his colleague Dr. Herbert Traut published “The Diagnostic Value of Vaginal Smears in Carcinoma of the Uterus” which forever changed the landscape of cancer screening for women (150). The Papanicolaou, or Pap smear, is now used worldwide for cervical and vaginal cancer screening, and its utility and efficacy continue to be validated as newer molecular technologies emerge, particularly testing for HPV DNA.

It should be noted that the utility of the Papsmear as a screening test has not been based on randomized, controlled trials. Being the first such screening test in the modern era, the Pap smear never had to prove its clinical benefit through an evidence-based approach, as many modern screening tests are evaluated today.

Despite a lack of level I evidence, the epidemiologic data is quite convincing (151–154). In developed countries, the incidence of cervical cancer has declined dramatically since the acceptance and utilization of cervical cytology based-screening. In the United States, rates declined from 36.3 per 100,000 in the 1930s to 7.2 per 100,000 in the beginning of the 21st century—a reduction of over 80%. The greatest rate of decline occurred between the 1950s to 1970s when rates dropped by over 3% per year (155). This correlates with the widespread adoption of routine cervical cancer cytology-based screening programs in the United States.

However, despite the widespread acceptance of cervical cancer screening tests, it is estimated that there are still over 12,000 new cases of cervical cancer diagnosed in the United States annually (156). Reports estimate that 20% to 30% of cases will be in women who have had proper screening (156,157). Thus, as effective as the Pap smear may be, it is evident that many cases of cervical cancer and premalignant lesions are still undetected, suggesting that its use as a screening test can be further optimized.

There are elements inherent to cytology that may inhibit its success as a screening test. This includes poor cellularity due to collection or transfer. Also, Pap smears may be read as unsatisfactory due to inflammation, scant cellularity, or obscuring blood thereby limiting diagnostic ability. The rate of unsatisfactory Pap smears ranges from 1% to 8% (158,159) and on reevaluation, a significant number of these show cytologic atypia, including high-grade lesions and carcinoma (159). This is usually overcome with liquid-based cytology, which is the more commonly used cervical cytology platform due to the ability to also perform molecular testing for pathogens like HPV from the same collection vial. One of the suggested

improvements to overcoming the human error is the ability to run HPV testing, which is highly sensitive and is not dependent on any subjective evaluation.

Despite rigorous international standards, the interpretation of cytology is subject to inter-observer variability. Discrepancies between low- and high-grade lesions among various laboratories and personnel may be as high as 15% (160). Moreover, it is well established that the category of atypical squamous cells of undetermined significance (ASC-US) remains a poorly reproducible category. Attempts have been made to improve its low positive predictive value including HPV triage testing, but nonetheless, much variability exists regarding cytologic interpretation (126,161).

Even under the best circumstances when sampling is adequate, and interpretation is performed by experienced cytologists, the sensitivity and specificity of the Pap smear at baseline limits its functionality as a screening test. A pooled analysis of European and Canadian studies noted that though the specificity of the Pap smear in detecting high-grade dysplasia (CIN 2 or greater) was 96%, the sensitivity was only 53% (162). In another systematic review, the sensitivity of the Pap smear ranged from 30% to 87% and specificity ranged from 86% to 100% (163).

Currently, the American Cancer Society (ACS), the American Society for Colposcopy and Cervical Pathology (ASCCP), and the American Society of Clinical Pathology (ASCP) recommend that women should begin cytology screening starting at age 21, regardless of risk factors (Table 7.2). Cytology should be performed every 3 years until age 30 (149). Based on modeling studies in this age group, and taking into consideration the natural history of the disease (including high rates of regression and long periods required before invasion), there is no increased risk of death due to cervical cancer associated with screening every 3 years versus every 2 years. Moreover, there is a 40% increase in the rate of colposcopy when screening is performed every 2 years compared to 3 years, with no increase in cancer detection with more testing (164).

At age 30, combined concurrent testing (or co-testing) with cytology and HPV testing is the preferred method of screening. If both tests are negative, screening can occur every 5 years (149). Co-testing improves sensitivity of detection of CIN 2/3 and lowers the false-negative rate of cytology alone (165,166). HPV testing also improves the detection of glandular lesions, which often go undetected with conventional cytology alone (167). If no HPV testing is performed, cytology alone every 3 years is acceptable. Women older than 65 and women with a previous hysterectomy for benign indications no longer need screening for cervical or vaginal cancer.

Table 7.2 Cervical Cancer Screening Recommendations

Age	Screening method	Comments
<21 years	No screening recommended	HPV testing is not recommended in this age group
21–29 years	Cytology alone every 3 years	HPV testing is not recommended in this age group
30–65 years	Preferred = “Co-testing” (HPV and Cytology) -or- Acceptable = Cytology alone every 3 years	
>65 years	No screening following adequate negative prior screening	If history of CIN 2+, continue screening for 20 years
After Hysterectomy	No screening	Applies only to women with no cervix and no history of CIN 2+
HPV Vaccinated	Follow age-specific recommendations (same as unvaccinated women)

Atypical Squamous Cells of Undetermined Significance

Figure 7.10 shows the distribution of Abnormal Cervical Cytology. ASC-US is the most common cytologic abnormality but the most poorly reproducible category (126). The rate of CIN 2/3 with ASC-US cytology varies depending on populations studied from 5% to 27%. However, because it is the

most common cytologic abnormality, half of all women with CIN 2/3 have a preceding diagnosis of ASC-US (168,169,170). Though only 0.2% of women with ASC-US cytology have invasive disease, women with cervical cancer often present with ASC-US cytology (171). Thus, further evaluation of women with this abnormality is warranted. The preferred approach to management of ASC-US is reflex high-risk HPV testing followed by colposcopy if the HPV test is positive (Fig. 7.9).

FIGURE 7.9. ASCCP Algorithms for Management of Abnormal Cytology.

FIGURE 7.10. Distribution of Abnormal Cervical Cytology.

Source: Adapted from Davey DD, et al. Bethesda 2001 implementation and reporting rates: 2003 practices of participants in the College of American Pathologists Interlaboratory Comparison Program in Cervicovaginal Cytology. *Arch Pathol Lab Med* 2004;128(11):1224–1229, with permission.

Among women who undergo reflex HPV testing, approximately 65% of women in their twenties will test HPV positive and only 31% of women over 30 years of age will be positive. HPV triage in women over 21 years of age with ASC-US cytology demonstrates high sensitivity for detection of CIN 2/3 and also reduces the number of unnecessary colposcopies by at least 50% (11). Approximately 15% of women with ASC-US cytology who are HPV positive have CIN 2/3 compared to less than 2% of women who are HPV negative (172). This is why it is recommended that a woman with an ASCUS HPV+ test undergo immediate colposcopy (HPV 173). Negative ASC-US cytology can be treated like a normal test and routine screening should follow. Annual cytologic follow up is not necessary (149).

Atypical Squamous Cells Cannot Exclude High-Grade SIL

Women with ASC-H cytology have a higher rate of CIN 2/3 than women with ASC-US (approximately 40% vs. approximately 15%, respectively) (168,172,174). The majority of specimens are HPV-positive and thus reflex HPV is not recommended; instead, immediate colposcopy should be performed (173).

Low Grade Squamous Intraepithelial Lesion

Roughly one-fourth of women with LSIL cytology have CIN 2/3, and most harbor a high-risk HPV infection (133). Therefore, colposcopy should be performed in all women with LSIL (Fig. 7.9). If no CIN 2/3 is identified, patients should be followed with either HPV testing in 1 year or repeat cytology at 6 and 12 months. The exception is postmenopausal women who have low rates of HPV infection and low rates of CIN 2/3 with LSIL cytology. In these women, HPV triage testing similar to women with ASC-US cytology is preferred (173).

High-Grade Squamous Intraepithelial Lesion

The rate of high-grade squamous intraepithelial lesion (HSIL) cytology is less than 1%, but it correlates strongly with high-grade cervical lesions (175). Management of HSIL includes either colposcopy or an immediate loop electrosurgical excisional procedure (LEEP) (Fig. 7.9). Up to two-thirds of women will have CIN 2/3 at the time of initial colposcopy for HSIL and over 90% of women will have CIN 2/3 when evaluated with an excisional procedure. Immediate LEEP is preferred in many institutions because of its cost-effective nature and reduced number of follow up exams (176,177).

Atypical Glandular Cells

Compared to atypical squamous cell cytology, atypical glandular cells (AGC) has a higher rate of both preinvasive and invasive disease. AGC is an uncommon diagnosis and is seen in less than 1% of cytologic specimens. Women older than 35 years of age are more likely to have invasive disease compared to women less than 35 years old. Overall, high-grade lesions, including AIS and invasive disease, are found in 9% to 38% of women with AGC (178,179). Following a diagnosis of AGC, colposcopy with endocervical sampling is recommended. Additionally, endometrial biopsy should be performed in women over the age of 35 or in women with risk factors for endometrial cancer (173).

Detection Methods

Molecular technologies for HPV detection have developed rapidly as routine clinical utility for such testing has expanded. The U.S. Food and Drug Administration (FDA) has approved five tests for detecting HPV. The first Hybrid Capture II (HCII) assay (Qiagen, Germantown, MD) was approved in 2003; it detects 13 high-risk HPV types through nucleic acid hybridization assays using signal amplification and chemiluminescence. In 2009, the FDA approved 2 additional HPV DNA tests: Cervista HPV HR (Hologic, Bedford, MA), which detects 14 high-risk types, and Cervista HPV 16/18 (Hologic, Bedford, MA), which detects HPV types 16 and 18. In 2011, the Cobas HPV test (Roche Molecular Systems, Pleasanton, CA) has been approved for the identification of HPV 16 and 18 while concurrently detecting 12 other high-risk HPV types. Most recently, the APTIMA HPV assay (GenProbe, San Diego, CA) was approved for cytology triage and cotesting. This assay detects the messenger RNA of the oncogenic E6 and E7 proteins of 14 high-risk HPV types (Table 7.3).

After over 60 years of cervical cancer screening with just the Pap smear alone, guidelines have been modified to reflect an improved understanding of the role of high-risk HPV in the development of cervical cancer and the role of HPV testing in cervical cancer screening.

The ASCCP recommends HPV testing in a variety of specific situations. These situations include triage of women 21 years or older with an ASC-US Pap smear, cotesting with cytology in women older than age 30, follow up after excisional procedures or ablation of CIN 2/3, management of postmenopausal women with LSIL, management of women with AGC on cytology, and follow-up for CIN 1 when it was preceded by a low-risk Pap smear (LSIL, ASC-US, ASC-H). Moreover, the ASCCP recommends genotyping assays, which specifically detect HPV 16 and 18, as a way to further triage women over the age of 30 with normal cytology and positive high-risk HPV tests. Women with negative cytology who are HPV 16 or HPV 18 positive should be referred for immediate colposcopy, whereas

Table 7.3 Cervical Cancer Screening

Name	Company	HPV Genotype Detection	Uses	FDA approval date
Digene Hybrid Capture 2 High-Risk HPV DNA Test	QIAGEN, Germantown, MD	16, 18, 31, 33, 35, 39, 45, 51, 52, 56, 58, 59, and 68	1. ASC-US triage 2. Co-testing in women >30 years old	March, 2003
Cervista HPV HR	Hologic, Bedford, MA	16, 18, 31, 33, 35, 39, 45, 51, 52, 56, 58, 59, 66, and 68	1. ASC-US triage 2. Co-testing in women >30 years old	March, 2009

those who are high-risk HPV-positive but HPV 16 and HPV 18 negative can be followed in a year with repeat cytology or HPV testing (149).

Primary HPV testing as the sole screening modality has been investigated in multiple international trials, and shows promise in upfront screening strategies (166,180,181). In general, it has demonstrated improved sensitivity compared to cytology, although specificity may be lower. Because of its improved specificity over HPV testing alone, cytology may be used as a follow-up test after a positive HPV test (182). Because no large trials have evaluated the most effective strategies in managing the results of HPV testing in the primary screening setting in the United States, HPV testing is not yet recommended in the United States for use as a primary upfront screening test.

Additional Screening Strategies

In addition to cervical cytology and HPV testing from liquid-based cytologic specimens, other innovative techniques are being used in populations with limited access to standard screening approaches. In an attempt to make high-risk HPV testing more efficient, less invasive, and less costly, self-HPV testing has developed. Self-sampling demonstrates high concordance with physician collected samples (183). Prospective trials involving women who did not attend routine cervical screening programs in the Netherlands showed that, because of a higher participation rates, detection rate of CIN was higher than in the regularly screened population (184,185).

In developing nations where the cost of frequent follow-up exams and testing is prohibitive, visual inspection tests have emerged as an important method of screening and treatment. With a bright halogen lamp, visual inspection with acetic acid (VIA) or Lugol's iodine (VILI) is performed and positive lesions are referred to colposcopy with directed biopsy. Additionally, positive lesions can be treated immediately, bypassing the need for follow-up colposcopy. This is an efficient method of screening and treatment, and health care providers can be trained easily in visual inspection, thereby further improving its feasibility (186). Although significant verification bias exists in a

see-and-treat strategy, pooled analysis of trials utilizing visual inspection performed in developing nations revealed a sensitivity of 62% to 80% and specificity of 77% to 84% to detect high-grade CIN (187).

VIA and VILI with see-and-treat strategies appears to be cost-effective. A study that modeled screening strategies in India, Kenya, Peru, South Africa, and Thailand showed that screening women once per lifetime with visual inspection effectively reduced cervical cancer mortality by over 25% at an acceptably low cost in relation to each nation's gross domestic product (188). Population-based studies on VIA have yielded mixed results. In a south Indian population, cervical cancer mortality was reduced by 25% with VIA compared to no screening (189). In the largest prospective trial enrolling over 130,000 women in rural India, one-time screening methods of HPV testing, cytology, and VIA were compared. Compared with a control group, only HPV testing reduced the rate of cervical cancer (190). Thus once per lifetime HPV testing in women over 30 has been proposed as an effective method of cervical cancer reduction in low-resource settings (190).

SECTION 6: HPV VACCINATION

With an improved understanding of the role of HPV infection in the natural history of preinvasive and invasive lesions of the lower genital tract, prophylactic vaccination has emerged as an important element in cervical cancer prevention (Table 7.4).

The L1 capsid protein, which is 1 of 2 viral capsid proteins of the HPV virus, is the primary target for prophylactic vaccination. Vaccines consist of recombinant L1 proteins that form virus-like particles (VLPs), which are combined with different adjuvants. Adjuvants stimulate the immune system and increase the response to vaccination and are aluminum based. VLPs primarily induce a humoral response with neutralizing antibodies, but they also induce cell-mediated immune responses. Neutralizing antibody responses are logs higher than that generated from a response to a new HPV infection.

Table 7.4 HPV Vaccines

	Gardasil ^a	Cervarix ^b
VLP Types	HPV 6, 11, 16, 18	HPV 16, 18
Adjuvant	Aluminum Salt plus monophosphoryl lipid A	Aluminum Salt
Injection Schedule	Three injections: 0, 2, 6 months	Three injections: 0, 1, 6 months
FDA Approval	Females: prevention of vaginal, vulvar, and cervical cancer and their premalignant lesions (HPV 16, 18) Females and males: preventions of genital warts (HPV 6 and 11), anal cancer and premalignant lesions (HPV 16, 18)	Females: prevention of cervical cancer and premalignant cervical lesions (HPV 16, 18)
Additional Benefits	Safe in lactation	Safe in lactation Efficacy against HPV 31, 33, 45

^aMerck & Co., Inc., Whitehouse Station, NJ, USA.^bGlaxoSmithKline, Rixensart, Belgium.

Currently, 2 vaccines are approved in the United States for the prevention of cervical cancer. The quadrivalent vaccine (Merck & Co., Inc., Whitehouse Station, NJ, USA) contains VLPs to HPV types 6, 11, 16, and 18 and the bivalent vaccine (Glaxo Smith Kline, Rixensart, Belgium) contains VLPs to HPV types 16 and 18.

The FDA originally approved the quadrivalent vaccine in 2006 for girls and women aged between 15 and 25 years for the prevention of cervical cancer caused by HPV types 16 and 18, precancerous genital lesions caused by HPV types 6, 11, 16, and 18 and genital warts caused by HPV types 6 and 11. The federal advisory committee on immunization practices (ACIP) recommended routine vaccination of all 11- and 12-year-old girls. The three shot vaccination series can begin as young as age 9, and can be given to women up to age 26. In 2008, the quadrivalent vaccine was also approved for the prevention of vaginal and vulvar cancer in this same population. The following year, its use was expanded to the prevention of genital warts due to HPV type 6 and 11 in boys and men aged between 15 and 25. In 2010, the FDA further expanded the indications to include the prevention of anal cancer and associated premalignant lesions caused by these same HPV types. In 2011, the ACIP recommended routine vaccination of all boys, ages 11 and 12. The vaccine series can be given to boys as young as age 9 and up through age 22 for most men. The FDA approved the bivalent vaccine in 2009 for the prevention of cervical cancer and precancerous lesions caused by HPV 16 and 18 in women from 15 to 25 years of age. The ACIP recommendations for the bivalent vaccine mirror those for the quadrivalent vaccine, except the bivalent vaccine is not approved for use in males.

Multiple phase III trials have been conducted to evaluate the efficacy of these vaccines (191–193). These trials were blinded, placebo-controlled trials with endpoints that included development of CIN as well as external genital lesions for the quadrivalent vaccine. In an international trial that enrolled over 17,000 women aged between 16 and 26, the quadrivalent vaccine was 99% effective in preventing HPV 16 and 18 preinvasive or invasive lesions in a 3-year follow up period in women who were HPV naive at baseline. In an intention-to-treat analysis where women with preexisting infections were included, there was considerably less efficacy against incident of CIN 2/3 or AIS due to any HPV type, thus proving that it works primarily as a prophylactic vaccine (192). This trial also showed that the quadrivalent vaccine was effective in preventing 96% of CIN 1, 100% of VIN 1 and 99% of condyloma in HPV naive women (191).

The four-year follow-up of a bivalent HPV vaccine trial, which enrolled over 18,000 young women, showed similar efficacy against development of CIN 3 and AIS. Specifically, efficacy

against HPV 16- and 18-mediated CIN 3 lesions was 100% in women who were HPV negative at the time of vaccination. The vaccine was also effective against other lesions caused by HPV types 31, 33, and 45, which are closely related to HPV 16 and 18 (194). Specifically, in women who were HPV-negative at the time of vaccination, there was 93% efficacy against all CIN 3, irrespective of HPV type, as well as 100% efficacy against all AIS (195). High rates of efficacy even in non-HPV 16- or 18-mediated lesions suggest that the vaccine's effects may be more far reaching. Of note, these high clinical efficacy rates were associated with high cross-protective immune responses as well (196). HPV vaccination has not been shown to be therapeutic against preexisting HPV infections. Therefore, the HPV vaccine is most effective if it is administered prior to the onset of sexual activity. Additionally, the vaccine is not infectious and does not contain anything that would be teratogenic and is considered teratogenicity category B. Routine pregnancy testing prior to administration is not necessary and lactating women can safely receive the vaccine (197). Based on the natural history of HPV infection and development of preinvasive and invasive disease, it may take at least 15 years before there is a significant impact on the incidence of CIN 2/3 and perhaps 30 years before there is a change in cervical cancer incidence.

HPV vaccination programs are being instituted worldwide. HPV vaccination presents unique challenges in both high- and low-resource settings, including an older age of vaccination, a 3-dose regimen at a high cost relative to other childhood vaccines, and potential socio-cultural concerns about HPV being a sexually transmitted disease. Uptake of vaccination seems to be most affected by coverage of the vaccine at the state or national level. In the United States, it is estimated that almost 50% of adolescents received at least 1 dose and only 32% received all 3. Vaccine uptake varies significantly by state, likely a reflection of variability of state funding (198). Worldwide, rates are slightly higher in other high-resource settings. In Manchester, UK, the uptake of 2 doses was reported at 55%; 3-dose coverage in southern Australia was 69% and in Denmark, 62% (199–201). Despite many barriers to HPV vaccination, it is apparent that when communities make a focused effort to promote vaccination through financial coverage or public health awareness, high levels of vaccine uptake are noted (202).

Over 85% of cervical cancer cases occur in the developing world (203), yet patients in these nations are less likely to receive HPV vaccination. Despite its high cost relative to other childhood vaccines, in nations with high incidence, emerging models suggest that vaccination is cost-effective (204). Moreover, HPV vaccination has recently been made more affordable

at a subsidized price of 5 US dollars per dose (198). This has prompted research into the most effective strategies for large-scale vaccination. In a large international trial of developing nations, HPV vaccination programs were integrated into pre-existing health-center-based and school-based vaccination

programs in communities in India, Peru, Uganda, and Vietnam. Remarkably, complete vaccination (i.e., all 3 doses) was achieved in 68% to 96% of eligible girls (198). This study confirmed that a range of HPV vaccine delivery strategies were effective in achieving HPV immunization among eligible girls.

SECTION II

DIAGNOSTIC AND THERAPEUTIC MODALITIES

CHAPTER

8

Perioperative and Critical Care

JAMES J. BURKE II ■ SCOTT C. PURINTON ■ HEATHER MACNEW

INTRODUCTION

Surgery remains the mainstay of treatment for women with gynecologic malignancies. Ultimately, outcomes of the surgical intervention rest with the gynecologic oncologist in concert with anesthesiologists, nursing staff, stomal therapists, physical therapists, pharmacists, social workers, and the social network/support of the patient as well as others. Careful assessment of the patient prior to surgery can lead to improved outcomes and minimize surprises in the postoperative period. Should the need arise, prudent consultation with other medical specialists prior to or following surgery can further enhance patient care, and result in better outcomes.

The chapter has been divided into (2) sections: preoperative care/risk recognition and postoperative care/critical care. Within each section, clinical information has been arranged by organ system and recommendations are based upon evidence (when available). The critical care section provides basic yet practical information for the reader so that comanagement of the critically ill gynecologic oncology patient with an intensivist may be seamless.

PREOPERATIVE RISK ASSESSMENT

Initial Preoperative Evaluation

At the initial consultation for patients with known or suspected gynecologic malignancies, the gynecologic oncologist should take a thorough history, assessing for comorbid conditions, which may impact perioperative risk (1). Similarly, a thorough physical examination, looking for signs of diseases of which the patient is unaware, will aid in finding diseases that can impact surgical outcome. Review of accompanying medical records and radiographs is important. Ultimately, patients who will benefit from surgery are identified and will be deemed operative candidates, operative candidates who need further evaluation from specialists prior to surgery, or inoperable candidates.

Subsequent discussions should focus on the course of treatment. If surgical, the planned operative procedure should be described to the patient in nonmedical terminology. Attendant risks of the procedure, as well as alternatives for therapy (if they exist), should be described to the patient. The length of time for the operation and length of anticipated hospital stay should be estimated for the patient and her family. Further, time to recovery from the planned operative procedure should be estimated for the patient. These elements of the treatment plan constitute *informed*

consent, and should be documented in the medical record by the physician at the initial consultation. Preferably, this “consenting” should be done before the patient is in the preoperative holding area on the day of her surgery. Should further evaluation be needed from a specialist (e.g., a cardiologist or a pulmonologist), a letter outlining the proposed surgical intervention should be sent to the consultant. However, the impact of these consultations, or “preoperative clearances,” on perioperative outcomes is unclear (2–4).

Ideally, preoperative laboratory testing will be dictated by findings from the history and physical examination. Unfortunately, unnecessary and inappropriate preoperative testing has been done in an effort to reduce poor perioperative outcomes. However, evidence to support this practice is lacking and the cost to complete these unnecessary tests has been estimated to be over \$3 billion (5). In order to standardize preoperative testing, evidence-based guidelines have been developed (6). The National Institute for Health and Clinical Excellence (NICE), an independent organization in the United Kingdom that produces evidence-based guidelines for the promotion of good health and treatment of disease, developed guidelines for preoperative testing. These guidelines take into account the patient’s age, type of surgery, associated comorbidities, and the American Society of Anesthesiologists (ASA) grade for anesthesia risk (7) (Table 8.1). St. Clair et al. performed a retrospective study assessing adherence to the NICE guidelines for preoperative testing in patients having gynecological surgery between 2005 and 2007. The authors found that among 1,402 patients evaluated, inappropriate preoperative testing resulted in costs over \$418,000 (8).

If the patient’s condition requires the possibility of a stoma(s) (colostomy or urostomy), consultation with an enterostomal therapist for marking of the planned stoma(s) should be considered. During this visit, the therapist will take into account the location of the patient’s waist, abdominal creases, how she wears her clothing, the types of clothing she wears, and the location of the future stoma when she stands or sits. In addition, the therapist can initiate education on the function and care of the stoma(s).

Should the proposed surgery result in a marked change of body image or possible sexual dysfunction (e.g., exenteration, radical vulvectomy, or vaginal reconstruction), consultation with prior patients who have successfully recovered from similar operations may be warranted. In addition, these patients may benefit from psychological counseling prior to their surgery.

Assessment of Cardiac Risk

Any gynecologic oncologist must be aware of the underestimation of cardiac disease in women when evaluating cardiac risk preoperatively. In the past decade, a great deal of literature has

Table 8.1 National Institute for Health and Clinical Excellence Recommendations for Preoperative Testing

Study	Age (years)	Recommendation
Chest X-ray	Any age	Cardiovascular surgery
	60 or older	Grade 4 surgery and ASA 3 or greater with cardiovascular disease
Electrocardiogram	16–39	ASA 2 or greater with cardiovascular disease or cardiovascular surgery
	40–59	As above, plus grade 4 surgery if ASA 2 or greater with renal disease, or ASA 3 with respiratory disease
	60–79	As above, plus grade 2 surgery if ASA 2 or greater with renal disease, or ASA 3+ with respiratory disease or grade 3 surgery or greater
	80 or older	Consider deferring if grade 1 surgery
Full blood count	16–59	ASA 3 with renal disease, or grade 3 or greater surgery
	60 or older	As above, plus grade 2 or greater surgery
Hemostasis	16 or older	Never recommend, may be considered
Renal function	15–59	ASA 2 or greater with renal disease, ASA 3 or greater with cardiovascular disease, ASA 2 or greater with cardiovascular disease with grade 3 or greater surgery, ASA 3 or greater with respiratory disease, with grade 3 or greater surgery
	60 or older	As above, plus ASA 2 with cardiovascular disease, with grade 2 or greater surgery, or any grade 3 surgery
Urinalysis	16 or older	Never recommended, may be considered

ASA, American Society of Anesthesiologists.

ASA grade: ASA 1, normal/healthy; ASA 2, mild systemic disease; ASA 3 severe systemic disease.

Surgery grade: grade 1, minor surgery; grade 2, intermediate surgery; grade 3, major surgery; grade 4, extensive surgery.

been published on this subject. In 2001, the National Heart, Lung, and Blood Institute (NHLBI) launched the Heart Truth Project to promote education about heart disease among women (9). Statistics have shown that only one of three primary physicians correctly cited coronary artery disease as a leading cause of death in women. Similarly, studies have demonstrated that women are less often counseled on cardiac risk factors, less often prescribed lipid-lowering medications, less often offered invasive procedures, and less often prescribed cardiac rehabilitation. There is a lack of health care provider knowledge of the guidelines for prevention of cardiovascular disease (CVD) in women (10). Further, compared to men, women who had a

Table 8.2 Multifactorial Index of Cardiac Risk

Risk factor	Points
S3 gallop or increased jugular venous pressure	11
Myocardial infarction in previous 6 months	10
More than 5 premature ventricular ectopic beats per minute	7
Rhythm other than sinus or premature atrial contractions	7
Age >70 years	5
Emergency noncardiac operative procedure	4
Significant aortic stenosis	3
Poor general health status	3
Abdominal or thoracic surgery	3
Possible total	53

myocardial infarction (MI) had a greater interval from onset of pain until arrival at hospital, were less likely to be treated with thrombolytics and β -blocking agents, were less often evaluated with invasive methods, had higher rates of reinfarction, and had greater mortality (9).

In the assessment of perioperative risk, cardiac risk factors are certainly one of the top concerns for clinicians. There have been a number of reviews and different systems created for the purposes of assessing cardiac risk for patients undergoing noncardiac surgery (10–13). Realize that approximately 1 in 12 patients (>65 years old) will have significant coronary artery disease (14). It is estimated that over 30% of patients undergoing major elective surgery have at least one cardiac risk factor (15).

Cardiac risk indices have been published by at least 10 different investigators (16). Goldman et al. published the Multifactorial Index of Cardiac Risk (MICR) in 1977 (17). This risk index was the first large, prospective, multivariate analysis of patients undergoing noncardiac surgery. They used definite endpoints of cardiac death, ventricular tachycardia, pulmonary edema, and myocardial infarction. The MICR involves nine independent risk factors to create a point risk index and predict morbidity and mortality (Tables 8.2 and 8.3). One weakness of this index is underestimating risk in vascular surgery patients. Nonetheless, these criteria have been validated and have stood the test of time. In response to a shift in the literature from calculation of risk with indices to clinical decision making, especially in regard

Table 8.3 Multifactorial Index of Cardiac Risk, Cardiac Risk Class, Morbidity, and Mortality

Cardiac Risk	Total Points	Morbidity (%)	Mortality
Class I	0–5	0.7	0.2
Class II	6–12	5.0	1.6
Class III	12–25	11.5	2.3
Class IV	>26	22.2	55.6

Table 8.4 Classification of CVD Risk in Women

Risk Status	Criteria
High risk	Established coronary heart disease Cerebrovascular disease Peripheral arterial disease Abdominal aortic aneurysm End-stage or chronic renal disease Diabetes mellitus 10-year Framingham global risk >20% ^a
At risk	≥1 major risk factors for CVD, including: Cigarette smoking Poor diet Physical inactivity Obesity, especially central adiposity Family history of premature CVD (CVD at <55 years of age in male relative and <65 years of age in female relative) Evidence of subclinical vascular disease (e.g., coronary calcification) Metabolic syndrome Poor exercise capacity on treadmill test and/or abnormal heart rate recovery after stopping exercise
Optimal risk	Framingham global risk <10% and a healthy lifestyle, with no risk factors

CVD, coronary vascular disease.

^aOR at high risk on the basis of another population-adapted tool used to assess global risk.

Source: Adapted from Mosca L, Banka CL, Benjamin EJ, et al. Evidence-based guidelines for cardiovascular disease prevention in women: 2007 update. *Circulation*. 2007;115:1481–1501, with permission.

to the need for preoperative evaluation, the American College of Cardiology/American Heart Association (ACC-AHA) guidelines were developed (18). Recently, the AHA updated guidelines for CVD prevention in women (19). This document provides risk classification of coronary vascular disease (CVD), based upon clinical criteria and/or the Framingham 10-year global risk score (20) (Table 8.4). This CVD risk stratification has not been assessed specifically for preoperative risk assessment, but provides classification of women who may need further (noninvasive or invasive) evaluation.

Clearly, the approach to the patient must include a careful history and physical examination. Initially, age greater than 70 years was thought to be a risk factor for cardiac morbidity, but a recent clinical trial showed no increased independent risk for cardiac complications (20). Any prior history of cardiac disease such as angina, MI, arrhythmia, congestive heart failure, or valvular disease must be evaluated. Patients with unstable angina, recent myocardial infarction, class III-IV heart failure, decompensated congestive failure, or aortic stenosis present the highest risk. These patients will likely require further invasive testing. Severe aortic stenosis must be identified preoperatively because the risk of perioperative morbidity is as high as 30% (21).

In patients without overt cardiac risks, other factors are considered to be helpful for uncovering subclinical disease. Classically, these risk factors are smoking, hyperlipidemia, hypertension, and diabetes mellitus.

In 2007, the ACC-AHA published revised guidelines to direct invasive, interventional evaluations (14). The classification defines clinical predictors as minor, intermediate, and major. In addition, the guidelines now utilize functional capacity in terms of metabolic equivalents (METs), with a level <4 being considered poor. The ability to climb one flight of stairs or walk up a hill would classify the patient in the >4 group (14).

Testing available for further evaluation includes both invasive and noninvasive methods. The routine resting electrocardiogram is a valuable screening tool for patients over the age of 40. It can potentially identify a prior myocardial infarction, which may prompt further evaluation of coronary artery disease. Echocardiography can predict postoperative congestive heart failure (CHF) in patients with ejection fractions (EFs) less than 35% (22). Unfortunately, echocardiography cannot reliably predict ischemia, but may be quite useful in the evaluation of valvular diseases and for follow-up of patients with known left ventricular (LV) dysfunction. Additionally, elevated preoperative brain natriuretic peptide (BNP) is an independent predictor of 30-day adverse cardiovascular outcomes after noncardiac surgery (23). Exercise or pharmacological stress testing provides valuable information for perioperative ischemic risk. Nuclear scintigraphy with evaluation of perfusion defects has shown a positive predictive value of 12% to 16% and a negative predictive value of 99% (24). Dobutamine stress echocardiography has shown similar predictive values.

The ACC-AHA recommendations provide a way to segregate patients who should have their surgery delayed for further cardiac evaluation because of a recent MI, who should have their CHF optimized, or who should optimize control of dysrhythmias. In selected patients, coronary revascularization, angioplasty, stent placement, or valve replacement may be prudent before the planned noncardiac surgery (18).

The risk of reinfarction after a recent MI is directly related to the interval between the MI and an event, which could precipitate an MI. However, these rates have been declining due to improved perioperative care. Reinfarction rates have dropped from 37% in patients undergoing noncardiac surgery within 3 months following MI to 5% to 10%, more recently. Reinfarction rates reduce further as the interval from the original MI increases, with rates of reinfarction being 2% to 3% and 1% to 2%, 4 to 6 months and greater than 6 months, following the acute event, respectively (25). Elective surgery should be postponed for 6 months following an acute MI, however an urgent operation may be performed 4 to 6 weeks after infarction if stress testing is favorable and the patient receives cardiac monitoring in the perioperative period.

Perioperative β -Blockade

In 1996, a multicenter, randomized, placebo-controlled trial was published that evaluated the use of β -blockade with atenolol versus placebo in patients undergoing noncardiac surgery. Although no differences in perioperative mortality or MI were seen, the atenolol group had significantly fewer ischemic episodes (24% vs. 39%). Furthermore, at 6 months and at 2 years, the atenolol group had decreased mortality (9 vs. 21 deaths) and decreased number of cardiac events (16 vs. 32) (26). The Peri Operative ISchemic Evaluation (POISE) trial showed that the use of β -blockers in the perioperative period reduces the risk of the composite outcome of cardiovascular death, nonfatal myocardial infarction, and nonfatal cardiac arrest at 30 days. However, it also shown that bradycardic episodes and hypotensive events result in an increase in death and strokes (27). Based on the findings of these studies, patients with or at risk for coronary artery disease may receive some benefit from perioperative β -blockade use; however, the clinician must be aware of the potential adverse outcomes.

PULMONARY RISK ASSESSMENT

Postoperative pulmonary complications represent a significant cause for morbidity and mortality in patients undergoing elective surgery. Approximately 25% of deaths within the early postoperative period (first week) are related to pulmonary issues. Pulmonary complications after major abdominal surgery range from 20% to 30% (28). Laparotomy results in a 45% decrease in vital capacity and a 20% reduction in functional residual capacity (FRC) (29). When the patient is in the supine position, FRC is reduced below alveolar closing volume (i.e., the volume at which point alveoli start closing), which results in atelectasis (30).

When examining risk factors for postoperative pulmonary problems, a number of issues surface. General medical status (e.g., functional status, obesity, nutrition) is related to postoperative pulmonary complications (PPCs) (31). A history of congestive heart failure, renal failure, poor mental status, and immunosuppression are all associated with a higher PPC rate (32). Surgical issues such as the type of procedure (open or minimally invasive), the type of incision (thoracic and upper abdominal being worse than midline or lower abdominal), duration of anesthetic (>2 hours), the use of a nasogastric tube (increased risk), and the use of parenteral (increased risk) versus epidural (decreased risk) analgesics are all correlated with PPC incidence (33). All patients undergoing noncardiothoracic surgery should be evaluated for the presence of the following risk factors for PPCs in order to receive pre- and postoperative interventions to reduce risk: chronic obstructive pulmonary disease (COPD), congestive heart failure, American Society of Anesthesiologists (ASA) class of II or greater, functionally dependent, and age older than 60 years (34). In terms of direct pulmonary risk factors, the most common preexisting pulmonary disease is COPD (32). These patients retain carbon dioxide, have poor gas exchange, and have an increased residual volume. Smoking, history of dyspnea, pneumonia, and sleep apnea are other risk categories. Patients with asthma and other restrictive lung diseases (low forced vital capacity [FVC] with normal forced expiratory volume in the first second of expiration [FEV₁/FVC ratio) have minimal increased risk for PPCs (33).

When interpreting the usual preoperative radiographic and laboratory values, several caveats must be kept in mind. A preoperative chest radiograph in normal adults has no predictive value other than providing essential baseline data for an at-risk patient. Arterial blood gas analysis in prospective trials has not been shown to be useful in providing risk stratification. However, it is useful in providing baseline data for patients with preexisting disease such as COPD (35). A low serum albumin (<35 g/L) is a powerful marker of increased risk and should be considered in patients with one or more risk factors for PPCs (36). Preoperative pulmonary function tests (PFTs) are rarely useful for risk stratification and not routinely indicated prior to surgery. A consensus statement from the American College of Physicians in 2006 recommended that preoperative PFTs or chest radiography may be appropriate in patients with a previous diagnosis of COPD or asthma (34). Such testing may provide valuable baseline data and aid in risk stratification for patients with moderate to severe COPD who are undergoing major abdominal surgery.

Perioperative strategies for reducing risk of PPCs include lung expansion techniques, smoking cessation, and optimization of gas exchange. Although preoperative and postoperative incentive spirometry has shown mixed results in reducing the rate of pulmonary complications, it continues to be widely recommended (37), and it should be considered as a preventive strategy for any patient undergoing laparotomy. In order to maximize patient compliance, preoperative counseling and education are necessary. Clearly, COPD must be optimized with control of infection and maximizing medical regimens. Reactive airway disease should be prevented with the use of perioperative inhalation therapy such

as β agonists. Steroid therapy is generally reserved for patients already utilizing them as part of their medical regimen. These steroid-dependent patients will need stress-dose steroids to prevent insufficiency (see “Adrenal Suppression” section below). Prophylactic antibiotics are not indicated in COPD patients to prevent pulmonary infections.

Smokers have significantly more postoperative complications including pneumonia, surgical-site infections, and death (38). Smoking-cessation programs have had an unclear effect on PPCs (39). Although the data consist of poorly controlled trials, it appears that short-term abstinence (<8 weeks from the time of surgery) may actually increase the complication rate (40). Abstinence for greater than 10 weeks showed complication rates similar to nonsmokers (41). Unfortunately, the long-term success rate of smoking-cessation programs is low, and in the case of malignancy, the gynecologic oncologist rarely has the opportunity to delay the operation for 8 to 10 weeks.

ENDOCRINOLOGIC RISK ASSESSMENT

Diabetes

The prevalence of diabetes has reached epidemic proportions in the United States. In 2011, the Centers for Disease Control and Prevention (CDC) reported that 25.8 million people or 8.3% of the population have diabetes (42). Diabetes accounts for the fourth leading comorbid condition among hospital discharges (43). One-fifth of surgical patients will have diabetes and people with known diabetes have a 50% risk of undergoing surgery at some point in their lifetime (44). Interestingly, one-third to one-half of patients hospitalized are unaware that they have diabetes and are currently receiving no treatment. It is only during preoperative evaluation for elective surgery or acute hospitalization that these patients will be diagnosed (45). Because of this prevalence, some authors have suggested that all surgical patients be regarded as dysglycemic until proven otherwise (46). Understanding the basic physiology of diabetes and how it impacts perioperative risk is crucial for the surgeon.

There are two types of diabetes. Type 1 diabetes occurs as a result of insulinopenia, with all type 1 diabetics being insulin dependent. In the absence of sufficient insulin, these patients develop ketoacidosis. Type 1 diabetics account for approximately 10% of all diabetics. Type 2 diabetes occurs as a result of insulin resistance and impaired insulin secretion. Type 2 diabetics may be treated with diet alone, oral hypoglycemic agents, noninsulin injectable medications, or insulin. These patients account for approximately 90% of all diabetics (47). However, approximately 30% of hospitalized patients will have a prediabetic condition consisting of impaired fasting glucose levels or impaired glucose tolerance (45). Thus, perioperative glycemic control will be dictated by known (or newly discovered) diabetic status.

When evaluating patients with known diabetes for surgery, attention should be directed toward the patient's diabetic status (i.e., type of glucose control; number of hypoglycemic events, etc.) and the long-term complications caused by diabetes since this end organ damage can impact perioperative outcome. Most complications of diabetes are related to microvascular changes, such as diabetic retinopathy, neuropathy, nephropathy, and CVD (48). In addition to a thorough history and physical examination, preoperative studies should include an electrocardiogram to rule out a prior “silent” MI (especially in patients with diabetes for more than 10 years), serum creatinine, blood urea nitrogen, urinary analyses to assess renal function and glycosylated hemoglobin (HbA_{1c}) to evaluate recent glycemic

control. HbA_{1c} levels reflect the level of hyperglycemia that red blood cells (RBC) have been exposed. Because the average lifespan of an RBC is 120 days, the HbA_{1c} is an indicator of glycemic control over that period of time (47). As mentioned earlier, because of the prevalence of dysglycemia among hospitalized adults in the United States, measurement of HbA_{1c} as a screening for diabetes, may identify patients with undiagnosed diabetes or impaired glucose metabolism (46). HbA_{1c} levels ≤6.5% are associated with good long-term glucose control and have been associated with decreased rates of infectious complications across a variety of surgical procedures (49,50). However, HbA_{1c} levels >6.5% are diagnostic for diabetes and evidence of poor glycemic control in known diabetics (51,52). Ultimately, the type of diabetes, preoperative glycemic control, the extent and magnitude of the intended surgery, the elective or emergent nature of said surgery, and other comorbid medical conditions will affect the metabolic changes these patients face intra- and postoperatively (46).

Another entity which has come to light in the last decade among hospitalized patients is that of stress induced hyperglycemia (SIH). This disease is defined as an inpatient fasting glucose measurement ≥126 mg/dL or a random glucose measurement of more than 200 mg/dL, which returns to normal after discharge (44,53). A growing body of evidence suggests that SIH and diabetic hyperglycemia are different diseases (54) and SIH confers a higher risk of adverse outcomes, such as an increased risk of in-hospital mortality (52,55,56) and longer lengths of stay compared to nondiabetic or hyperglycemic diabetic patients (53).

The armamentarium available for treatment of diabetes has increased over the last decade. Type 1 diabetics will most likely be using a combination of insulin therapies for glycemic control, whereas type 2 diabetics may be on oral therapy alone, insulin therapy alone, injectable noninsulin therapy alone, or some combination therapy of all the aforementioned agents. Table 8.5 outlines these drugs and timing for stopping these medications prior to surgical procedures because of the pharmacological half-lives of these drugs (57).

The physiologic changes that diabetic patients encounter during surgery result in a hyperglycemic state. The stress of surgery increases secretion of epinephrine, norepinephrine, cortisol, and growth hormone, all of which directly antagonize insulin action (46–48). In addition, gluconeogenesis and lipolysis are increased with mobilization of glucose precursors, and a net protein catabolism ensues. Glycemic control perioperatively will depend upon the type of diabetes or impaired glucose tolerance the patient has, as well as the medications that have/have not be utilized to control such disease states. Recently the Clinical Guidelines Subcommittee of The Endocrinology Society published treatment guidelines for non-critically ill patients hospitalized and subsequently found to be hyperglycemic (known diabetes versus unknown). The authors would direct the reader to review these guidelines, but recommendations from this group, for perioperative care of patients with hyperglycemia undergoing surgical interventions, are listed in Table 8.6 (58).

There are several case-control studies that demonstrate an increased risk for adverse outcomes in patients undergoing elective noncardiac surgery who have either preoperative or postoperative hyperglycemia (59–63). Postoperative glucose levels greater than 200 mg/dL are associated with prolonged hospital stays and increased risk of postoperative complications including wound infections and cardiac arrhythmias (60–62). Although diabetic patients with vascular disease are at risk of silent postoperative MI and acute renal failure, postoperative infections (respiratory, urinary, wound infections, etc.) account for about two-thirds of all postoperative complications and 20% of all postoperative deaths among diabetics undergoing surgery (49). Hyperglycemia has been shown to impair phagocytic function and chemotaxis of granulocytes when glucose levels are higher than 250 mg/dL (64).

Medication Type	Night before Surgery	Morning of Surgery
Oral Agents		
Sulfonyl-urea		Hold
Glyburide	Give with meal	
Glipizide		
Glimepiride		
Metformin (contraindicated in women with creatinine levels >1.4)	Hold	Hold; can induce lactic acidosis and should be held in patients' procedures that require IV contrast
Thiazolidinediones	Hold	Hold; Can cause fluid retention in the postoperative period
Rosiglitazone		
Pioglitazone		
Meglitinides	Give with meal	Hold
Repaglinide		
Nateglinide		
α Glucosidase inhibitors	Give with meal	Hold
Acarbose		
Miglitol		
Dipeptidyl peptidase-IV inhibitor	Give with meal	Hold
Sitagliptin		
Noninsulin Injectable		
Incretin mimetics	Give 30–60 minutes before meal	Hold
Exenatide		
Amylin analog	Give immediately before meal	Hold
Pramlintide		
Insulin		
Regular Insulin	Give full dose	Give half dose
Humulin ®R		
Novolin ®R		
ReliOn ®R		
NPH Insulin	Give full dose	Give half dose
Humulin ®N		
Novolin ®N		
ReliOn ®N

Perioperative management of diabetes mellitus. Physicians' Information and Education Resources. American College of Physicians, 31 Aug. 2009, 26 Apr. 2012. <http://pier.acponline.org/physicians/public/periopr879/tables/periopr879-tl.html>, with permission.

Although glycemic control is important, the jury is still out on when control should be achieved (pre-, intra-, or postoperatively or throughout the entire perioperative period), what glucose levels should be achieved for maximum benefit, and which insulin regimen is most effective (46). The landmark publication by Van den Berghe et al. in 2001 showed, in a randomized, prospective fashion, that aggressive glycemic control through intensive insulin therapy (IIT) (maintaining glucose levels between 80 and 110 mg/dL) versus conventional insulin therapy (glucose levels between 180 and 200 mg/dL) in critically ill postoperative patients (more than 60% were cardiac surgery patients) reduced episodes of septicemia and in-hospital mortality by 46% and 34%, respectively (65). Despite the enthusiasm for tighter glucose control, subsequent studies over the last decade, with a heterogeneous population of acutely ill patients, have failed to confirm the results of Van den Berghe's work (46,53). In fact, the multinational, multidisciplinary Normoglycemia in Intensive Care Evaluation and Survival Using Glucose Algorithm Regulation (NICE-SUGAR) trial in 6104 ICU patients reported increased mortality rates (27.5% [IIT] vs. 24.9% [control]) in patients who were kept at blood glucose levels of 81 to 108 mg/dL versus <180 mg/dL. The increased mortality was driven by increased rates of

Table 8.6 Perioperative Blood Glucose Control: An Endocrine Society Clinical Practice Guideline

Recommendation Number	
5.3.1	All patients with type 1 diabetes who undergo minor or major surgical procedures receive either continuous insulin infusion or subcutaneous basal insulin with bolus insulin as required to prevent hyperglycemia during the perioperative period
5.3.2	Patients with diabetes should discontinue oral and noninsulin injectable antidiabetic agents before surgery with initiation of insulin therapy in those patients that develop hyperglycemia during the perioperative period
5.3.3	When instituting subcutaneous insulin therapy in the postsurgical setting, basal (for patients who are NPO) or basal bolus (for patients who are eating) insulin therapy is the preferred approach. Sliding scale insulin (SSI) should not be used

Source: Umpierrez GE, Hellman R, Korytkoski MT, et al. Management of hyperglycemia in hospitalized patients in non-critical care setting: an Endocrine Society Clinical Practice Guideline. *J Clin Endocrinol Metab*. 2012;97:16–38.

hypoglycemia (blood glucose <40 mg/dL) among patients with the tightest blood glucose control (6.8% [IIT] vs. 0.5% [control], respectively) (66). Because of the NICE-SUGAR study, and others (53), recommendations for blood glucose targets have relaxed somewhat depending upon the setting of the patient. Intravenous (IV) insulin therapy should be instituted in critically ill patients when blood glucose levels exceed 180 mg/dL, and for non-critically ill patients when blood glucose levels exceed 140 mg/dL (67), to maintain blood glucose at these levels while minimizing hypoglycemia. Attaining these levels of glycemic control will depend upon the patient's type of diabetes, her medical condition, and her oral intake status. Individual institutional policy will vary as to where patients may receive IV insulin therapy (ICU vs. step-down units vs. routine hospital floors). If the patient is receiving IV insulin, then transition to a subcutaneous route must be started before discontinuing the IV route. Most patients can be converted to long-acting basal insulin, with the dose usually being 50% to 80% of the prior day's IV insulin dose. An insulin regimen utilizing a subcutaneous basal/bolus approach outperforms traditional sliding scale regular insulin regimens. Umpierrez et al. expanded their previous work (68) by conducting a prospective randomized trial comparing subcutaneous basal/bolus insulin replacement to traditional subcutaneous sliding scale insulin (SSI) replacement for patients with type 2 diabetes undergoing general surgery, not expected to be admitted to the ICU, and whose glucose levels exceeded 140 mg/dL. In the group randomized to the basal/bolus insulin, the starting daily dose was 0.5 U/kg/day, with half of the dose being given as basal insulin (insulin glargine) once daily and half given as rapid-acting insulin analog (glulisine) in fixed doses prior to meals. If the patient was NPO, then the insulin glargine dose was given and the insulin glulisine was held until meals were resumed. For supplementation, the rapid-acting analog was used. Among the 211 patients studied, those in the basal/bolus group received higher daily doses of insulin, had lower daily mean blood glucose levels (27 mg/dL lower), had the same risk of hypoglycemic episodes (blood glucose levels <40 mg/dL), and more often achieved the glycemic goal of <140 mg/dL.

Table 8.7 Basal/Bolus Insulin Treatment Protocol

Starting Insulin Doses	Supplemental Insulin (Insulin Glulisine)				Insulin Adjustment
Discontinue all oral anti-diabetic and noninsulin injectable medications	Give supplemental insulin glulisine according to the sliding scale (below) for blood glucose >140 mg/dL				If the fasting and predinner BG is between 100–140 mg/dL and no hypoglycemia the previous day: no changes
Starting total daily dose (TDD): 0.5 units/kg-actual body weight	If patient is able and expected to eat, give supplemental glulisine before each meal and at bedtime following the “usual” column				If the fasting and predinner BG is between 140–180 mg/dL and no hypoglycemia the previous day: increase insulin TDD by 10% every day
*Reduce TDD to 0.3 units/kg actual body weight in patients ≥70 years of age and/or serum creatinine ≥2.0 mg/dL	If the patient is not able to eat, give supplemental glulisine every 6 hours (6–12–6–12) following the “sensitive” column				If the fasting and predinner BG is >180 mg/dL and no hypoglycemia the previous day: increase insulin TDD by 20% every day
Give half of the TDD as insulin glargine, at the same time once daily and half as insulin glulisine in three equally divided doses before each meal. Hold insulin glulisine if patient not able to eat	Blood Glucose (mg/dL)	Insulin Sensitive (units)	Usual (units)	Insulin Resistant (units)	If the fasting and predinner BG is between 70–99 mg/dL and no hypoglycemia: decrease insulin TDD by 10% every day If the patient develops hypoglycemia BG <70 mg/dL: decrease insulin TDD by 20%
	141–180	2	4	6	
	181–220	4	6	8	
	221–260	6	8	10	
	261–300	8	10	12	
	301–350	10	12	14	
	351–400	12	14	16	
	>400	14	16	18	

TDD-total daily dose; BG-Blood Glucose

In addition, the basal/bolus group had fewer wound infections, pneumonias, episodes of bacteremia, respiratory failure, and acute renal failure as compared to the SSI group. There also was a nonsignificant trend toward fewer postsurgical ICU admissions and shorter ICU stays than in the SSI group (69). Table 8.7 demonstrates the basal/bolus method to control hyperglycemia in type 2 diabetics postoperatively.

Thyroid Disorders

When patients give history of hypothyroidism or hyperthyroidism during evaluation for surgery, thyroid-stimulating hormone (TSH) and thyroxine (T4) levels should be obtained. The primary objective is to determine if the patient is euthyroid or not, prior to surgical intervention so as to avoid the complications of myxedema or thyroid storm in the postoperative period.

Hypothyroidism is a common condition in the United States, affecting approximately 1% of all patients and 5% of the population over the age of 50 and it develops 10 times more often in women than men (70). Decision to operate on patients with hypothyroidism will depend upon the level of hypothyroidism and the urgency of the surgery. Hypothyroidism can influence many physiologic functions, such as myocardial function, respiration, gastrointestinal motility, hemostasis, and free water balance (46,71). Although there have been no prospective, randomized studies looking at the surgical outcome of hypothyroid patients versus controls, several retrospective case-matched control studies have evaluated hypothyroid patients undergoing surgery. A study by Weinberg et al. demonstrated no differences between hypothyroid and euthyroid controls for perioperative complications. In addition, no differences in outcome were seen when hypothyroidism was stratified by thyroxine levels. The investigators concluded that patients with mild to moderate hypothyroidism should not be denied needed surgery in order to correct the metabolic problem. They further

stated that insufficient numbers of patients with severe hypothyroidism precluded recommendations for perioperative care of these patients (72). In another retrospective study, Ladenson et al. reviewed perioperative complications among hypothyroid patients undergoing surgery, finding more intraoperative hypotension in noncardiac surgery, more heart failure in cardiac surgery, and more gastrointestinal and neuropsychiatric complications. They also noted that patients were unable to mount fever in the face of infection, although infection rates were not different. Further, no differences were found in the duration of hospitalization, perioperative arrhythmias, delayed anesthesia recovery, pulmonary complications, or mortality (73).

Patients with mild to moderate hypothyroidism requiring urgent surgery may have it without delay. These patients may have more minor complications of ileus, postoperative delirium, or infection without fever. Patients with severe hypothyroidism (myxedema coma, decreased mentation, pericardial effusions, heart failure, or very low levels of thyroxine) who are to undergo urgent/emergent surgery will need intravenous levothyroxine (200–500 µg given during 30 minutes) followed by daily doses of 50 to 100 µg intravenously. These patients will likely need stress-dose glucocorticoids (see “Adrenal Suppression” section) started prior to, during, and continued after surgery due to coexisting adrenal insufficiency (or due to the fact that intravenous replacement with levothyroxine may precipitate adrenal insufficiency) (46,73,74).

Myxedema coma is a rare condition, with an incidence of 0.22 per million patients per year. Most of the cases (80%) occur among hospitalized, elderly (older than 60 years) women with long-standing hypothyroidism, but it can occur at any age (75). A majority of the cases will occur in the postoperative period due to inciting causes such as infections, cold exposure, sedatives, analgesics, and other medications. The mortality from this disease is high (80%), but has been decreasing in recent years due to increased awareness, testing, and improved perioperative care (76–78). Myxedema coma is characterized by severely depressed

mental status, seizure, hypothermia, bradycardia, hyponatremia, heart failure, and hypopnea. Although maintenance of normothermia by warming is tempting, the resulting vasodilatation may cause cardiovascular collapse in patients with intravascular volume depletion, cardiac insufficiency, and pericardial effusion/tamponade, and should be performed carefully if at all (76). Myxedema coma is a medical emergency and necessitates urgent administration of levothyroxine. An initial intravenous bolus of 200 to 500 µg should be given, followed by 50 to 100 µg intravenously daily. Dehydration is frequently present and aggressive volume resuscitation with dextrose and normal saline should be instituted. Intravenous glucocorticoids should be administered (50 mg hydrocortisone IV, 4 times daily) because of frequent adrenal insufficiency. Resolution of symptoms, if properly treated, should begin within 24 hours.

Patients using thyroid replacement preparations can have their doses held during the immediate postoperative period until they are able to tolerate oral intake, as the half-life of these drugs is 5 to 9 days (71).

The causes of hyperthyroidism are many, but the most common cause is Graves disease. This autoimmune disorder, caused by an antibody directed to thyroid-stimulating hormone receptors, results in increased thyroid hormone production. The clinical signs of hyperthyroidism include tachycardia, atrial fibrillation, fever, tremor, goiter, and ophthalmopathy (47). Most complications occurring in hyperthyroid patients undergoing surgery involve cardiac function, as T4 and T3 have direct inotropic and chronotropic effect on the heart and a vaso-dilatory effect on peripheral vasculature, resulting in the activation of the renin-angiotensin-aldosterone system. All of these events result in a high cardiac output state, which increases cardiac work and oxygen requirements and can result in myocardial infarction (75). Arrhythmias are very common in the face of hyperthyroidism, with atrial fibrillation occurring in 10% to 20% of patients (79–82). Again, level of control prior to the operation will determine the perioperative outcome for the patient. Patients with controlled hyperthyroidism should be instructed to take their antithyroid medications in the morning of the day of surgery. Patients with mild hyperthyroidism may have surgery with preoperative beta-blockade. However, patients with moderate or severe disease should have surgery canceled until a euthyroid state is attained (83).

The greatest perioperative risk for patients who have undiagnosed hyperthyroidism or who are inadequately treated, is a rare, yet life-threatening condition known as thyroid storm. This “thyroid emergency” usually occurs intraoperatively or 48 hours postoperatively. The mortality of thyroid storm is 10% to 75% and requires treatment in a critical care environment (70). Symptoms are nonspecific and include hyperpyrexia, tachycardia, delirium, nausea and vomiting, and diarrhea (84). Treatment of thyroid storm is aimed at stopping production of thyroid hormone and treating the systemic effects of the decompensated patient. Antithyroid medications such as carbimazole, methimazole, and propylthiouracil (PTU) are used to inhibit the new synthesis of thyroid hormones. Unfortunately, there are no IV preparations for these compounds, so they must be administered enterally or per rectum as retention enemas or suppositories. Recent guidelines from the American Thyroid Association and the Association of Clinical Endocrinologists recommend that propylthiouracil be started with a loading dose of 500 to 1000 mg followed by 250 mg every 4 hours, and methimazole should be administered at daily doses of 60 to 80 mg (85). Administering these drugs in this sequence will provide more rapid clinical improvement because propylthiouracil has the added advantage of inhibiting conversion of T4 to T3, which methimazole does not do. These drugs prevent synthesis of new thyroid hormone, but will not stop release of stored thyroid hormone. Either inorganic iodine or lithium carbonate (for patients who are allergic to iodine; 300 mg orally every 6 hours) must be given. Lugol’s solution or a saturated solution of potassium iodide (3–5 drops

orally, every 6 hours) may be used, but must not be given sooner than 1 hour after the administration of the thionamide dosage; otherwise thyroid hormone synthesis will be enhanced by the iodine treatment. In severe cases of thyroid storm, plasmapheresis and therapeutic plasma exchange may be needed. β -blockade is critical to ameliorate the manifestations of thyroid excess and does so by correcting the heart rate, reducing cardiac oxygen demand, decreasing agitation, convulsions, psychotic behavior, and tremors. Propranolol is the most commonly used agent and dosages of 60 to 80 mg given orally every 4 hours or 0.5 to 1 mg IV followed by subsequent doses of 2 to 3 mg every several hours are recommended. Another theoretic benefit of β -blockade is the inhibition of conversion of T4 to T3. One other medication which has a high therapeutic benefit is the administration of corticosteroids, which not only inhibits the conversion of T4 to T3, but also treats adrenal insufficiency which may have occurred due to the rapid turnover of cortisol. Acetaminophen is preferred to salicylates, as the latter may exacerbate thyrotoxicosis by decreasing thyroid protein binding and increasing free T3 and T4. Finally, a thorough search for the precipitating cause of the thyroid storm should be undertaken immediately, with the most common cause in the perioperative period being infection (75).

Adrenal Suppression

How patients respond to stress is directly related to the hypothalamic-pituitary axis (HPA), and any defect in this cycle can have dramatic effects in the perioperative period. The most common cause of primary adrenal insufficiency (AI) is autoimmune adrenalitis, where the adrenal cortex is destroyed and the patient’s endogenous production of glucocorticoid steroids is reduced or ceases. Secondary AI is characterized by atrophy of the adrenal cortex as a result of deficient adrenocorticotrophic hormone (ACTH) stimulation. The most common cause of secondary AI is administration of exogenous corticosteroids which feeds back to cause a decrease in hypothalamic corticotropin-releasing hormone and subsequent decreased pituitary ACTH secretion. Although there is remarkable variability in individual response to a particular dose and length of treatment with steroids, in general, any patient who received the equivalent of 20 mg per day of prednisone for more than 5 days is at risk for HPA suppression. If the duration of steroid treatment is 1 month or longer, the patient will have HPA suppression, which can last for 6 to 12 months after stopping therapy. Whereas an equivalent dose of prednisone 5 mg (or less) for any period of time will not usually suppress the HPA axis (86–88). Assessment of adrenal function (ACTH stimulation tests) in the perioperative period has not been shown to be sensitive or specific in identifying patients who are at risk for AI and who might respond to supplemental corticosteroids (89–92).

Recently, Marik and Varon performed a meta-analysis of the world literature concerning perioperative stress doses of corticosteroids for patients who take corticosteroids chronically. Their search revealed two randomized controlled trials (RCTs) and seven cohort studies, for a total of 315 patients. Although the number of patients is small, the two RCTs showed no differences in the hemodynamic profiles of patients receiving stress doses of corticosteroids, compared to patients receiving only their usual daily dose of corticosteroid. Similarly, in 5 of the 7 cohort studies, patients who continued to receive their usual daily doses of corticosteroids without additional stress doses, did not develop unexplained hypotension or adrenal crisis perioperatively. The remaining 2 cohort studies each had 1 patient who stopped their usual daily dose of corticosteroid preoperatively, and each developed unexplained postoperative hypotension, which responded to hydrocortisone and fluid therapy. The authors recommend that patients receiving therapeutic doses of corticosteroids, who undergo surgery, do not routinely need

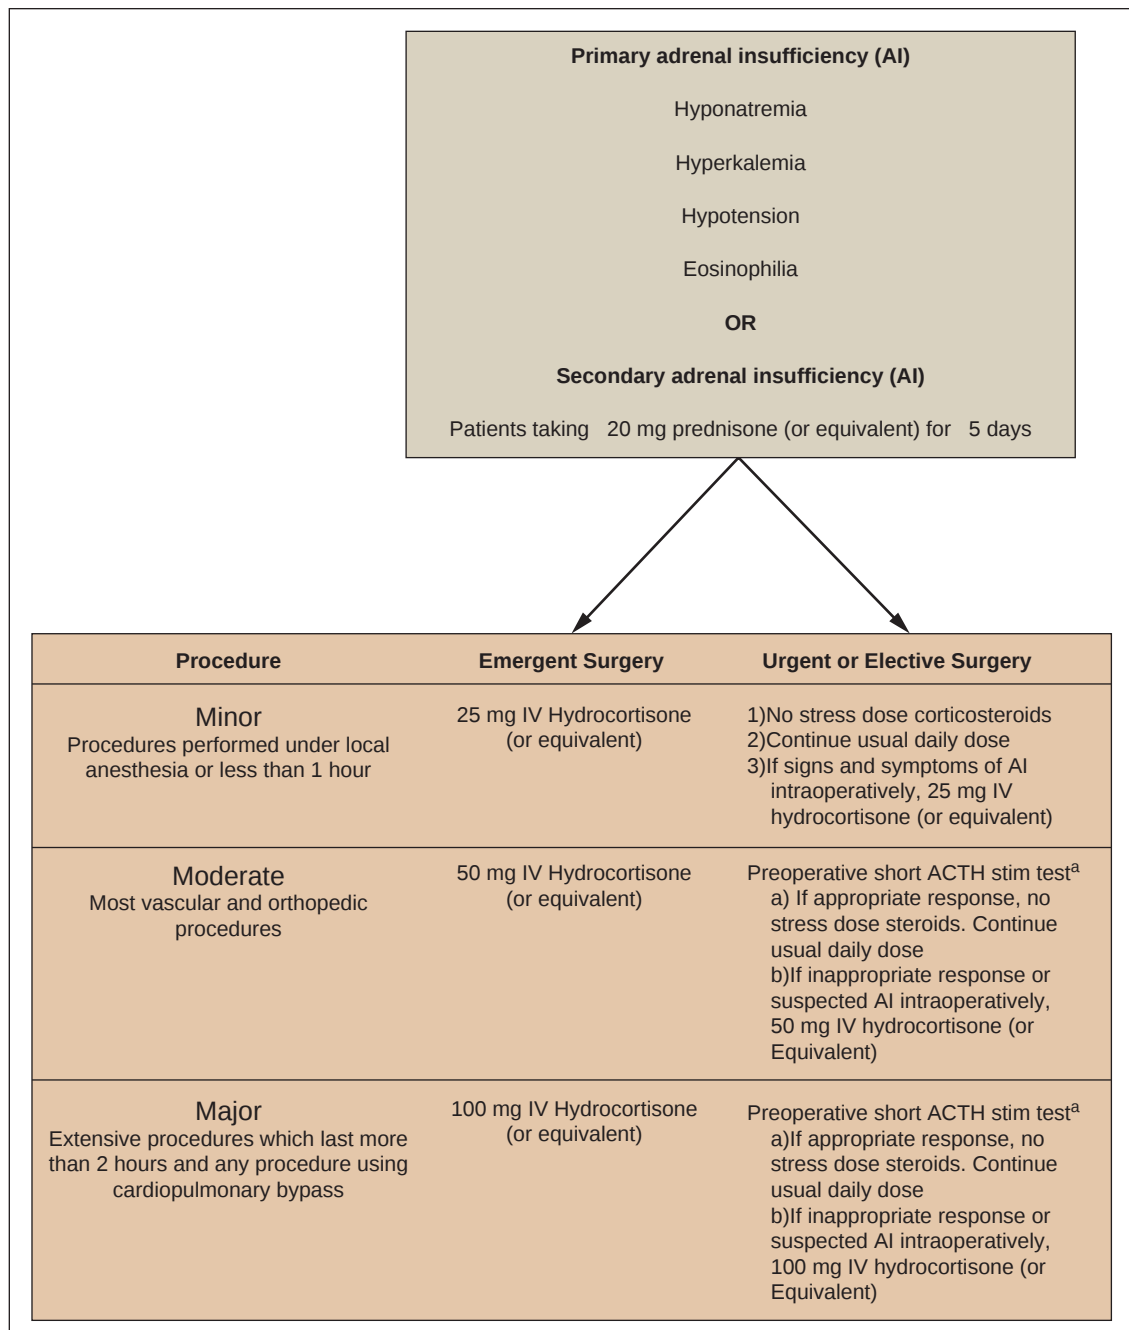

FIGURE 8.1. Algorithm for adrenal insufficiency.

^aThe short ACTH stimulation involves IV administration of 250 µg synthetic ACTH (Cortrosyn™, cosyntropin) followed by plasma cortisol collection 30 minutes later. Normal cortisol levels after stimulation greater than 18 µg/dL.

When given intraoperatively, steroid doses are continued every 8 hours for 48 hours.

Source: Adapted from Kohl BA, Schwartz S. How to manage perioperative endocrine insufficiency. *Anesthesiol Clin*. 2010;28:139–155, with permission.

stress doses of corticosteroids as long as their usual daily dose is continued. In addition, adrenal function testing is not recommended for these patients because the test is overly sensitive and does not predict which patient will develop adrenal crisis. Further, patients who have primary adrenal insufficiency and who are taking physiological replacement doses of corticosteroids will require supplemental stress doses of corticosteroids in the perioperative period (93).

Figure 8.1 outlines an algorithm that may be helpful in guiding clinicians in their decision-making about stress-dose steroids for patients who take them chronically. Giving stress dose glucocorticoids needs to be weighed against the potential side effects

of the drug (such as poor wound healing, fluid retention, and increased risk of infection) versus the benefits of supporting the HPA axis in a surgically stressed patient.

RENAL RISK ASSESSMENT

Chronic kidney disease (CKD) affects over 13 million Americans (20 years and older; CKD stage 2 or worse) (94), with most having a glomerular filtration rate (GFR) of less than 60 mL/min/1.73 m² (95). The most common form of renal failure facing the

surgeon is acute kidney injury (AKI) occurring during the postoperative period, which will be discussed below in the section on postoperative/critical care. Since 2002, a uniform classification system for CKD was introduced, stratifying CKD into 5 stages based on estimation of GFR and documentation of renal injury (95). Class 5 CKD, or end-stage renal disease (ESRD), includes patients who require renal replacement therapy (usually dialysis) for treatment (94). With the aging population, increasing prevalence of diabetes and hypertension, and advances in dialytic therapy, the number of patients living with CKD is increasing (94). Therefore, surgeons must be cognizant of the potential perioperative risks associated with these patients.

The predominant causes of CKD are diabetes and hypertension, accounting for 71% of all patients who are dialysis dependent (94). Patients with these underlying diseases tend to have other comorbid conditions such as coronary artery disease and peripheral vascular disease. Evaluation of CKD patients undergoing surgery should focus on four areas: cardiac evaluation, fluid and electrolyte management, anemia, and bleeding diatheses. Of course, glycemic control for diabetics and blood pressure control for hypertensive patients is obvious.

CVD has long been recognized as the leading cause of death among ESRD patients, which occurs in 50% of patients (94,96, 97). However, patients with other stages of CKD, even minor derangements, have an increased risk of CVD. A recent study correlated stage of CKD with odds ratios (ORs) for cardiovascular risk, demonstrating a graded increase in risk with increasing stage of CKD (OR-15 for Stage I to OR 20 to 1000 for stage V) (97). The disease factors which contribute to CVD among CKD patients include microalbuminuria/proteinuria, hypertension, diabetes, dyslipidemia, and smoking (98). In addition, many CKD patients will have coronary artery disease (23% to 40%) (99–101), and many ESRD patients (70% to 80%) will develop ventricular hypertrophy due to hypertension and severe anemia. This hypertrophy results in a decreased myocardial capillary density and diastolic and systolic dysfunction, all of which leads to disturbances in intra-ventricular conduction, electrical excitability, and ventricular arrhythmias (102). Therefore, these patients may benefit from a formal cardiac clearance from a cardiologist prior to surgical intervention.

The capacity of the failing kidney to maintain volume and electrolyte homeostasis is achieved through adaptive processes, which are limited in their ability to respond to physiological stresses, placing well-compensated patients, in the premonitory state, at increased risk of fluid and electrolyte disturbances during the perioperative period (103). Intraoperative and perioperative fluid management in the patients with CKD must therefore take into account the reduced capacity for both water excretion and conservation. Excessive free water administration must be avoided to prevent iatrogenic hypotonicity, while providing sufficient free-water to prevent hypertonicity. Electrolyte status should be monitored frequently and water administration adjusted if hypo- or hypernatremia ensues (104). ESRD patients who are dependent upon dialysis will need to be euolemic prior to surgery. Thus, communication with the patient's nephrologist is paramount. Details about the operation should be discussed, with planned preoperative dialysis (without heparin 24 hours prior to surgery) and postoperative dialysis on the day of surgery for large intraoperative fluid loads. Electrolytes should be monitored in the immediate postoperative period, with hyperkalemia being aggressively managed with dialysis, or medically if necessary. Acute hyperkalemia may be treated with glucose and insulin, which will drive the Na/K-ATPase pump resulting in an increase of intracellular potassium and lowering of extracellular potassium. Ten milliliters of calcium gluconate can afford cardioprotection and membrane stabilization in patients with abnormal electrocardiograms (ECGs) (105). Decreasing total body potassium is the final step in the treatment of hyperkalemia. In non-oliguric patients, renal potassium excretion may be enhanced

with loop-acting diuretics. Sodium polystyrene sulfonate (Kionex®, Kayexalate®) may be used as an exchange resin in the gastrointestinal tract. Forty grams dissolved in 80 mL of sorbitol (or more to promote elimination) and given orally will bind one millimole of potassium for each gram given. Alternatively, 50 to 100 g of sodium polystyrene sulfonate may be dissolved in 200 mL of water and may be given rectally as a retention enema by inserting a Foley catheter into the rectum and filling the balloon (104). These administrations should be repeated every 2 to 4 hours until the potassium level is in a normal range (see section below on potassium derangements). Caution with the use of this resin in postoperative patients is urged, as intestinal necrosis has been reported (106).

Most patients with CKD have or will develop anemia due to erythropoietin deficiency during the course of their disease and, prior to the introduction of erythropoietin stimulating agents (ESAs), were transfusion dependent. In recent years, the use of ESAs has come under scrutiny. Recent reviews have demonstrated that raising the hemoglobin levels above 11 g/dL in patients with CKD resulted in a 1.14-fold increase in the odds ratio of death. These results highlight the need to carefully manage hemoglobin levels with ESAs within a recommended range of 9 to 11 g/dL (107,108). In urgent situations, transfusion of blood is necessary to maintain hemoglobin prior to and during surgery.

CKD patients have an increased risk for bleeding complications. Platelet dysfunction caused by renal failure is multifactorial, with retained uremic toxins, abnormal binding of von Willebrand factor, abnormal platelet arachidonic acid metabolism, and excess vascular prostacyclin and nitric oxide production all being implicated (109). The bleeding time provides the best correlation with risk of clinical bleeding in CKD patients. If a patient has demonstrated prior bleeding because of uremic platelet dysfunction, these patients must be treated with 1-deamino-8-D-arginine vasopressin (dDAVP) intravenously, or intranasally and with cryoprecipitate to prevent bleeding during surgery (110). In addition, patients may be treated with intravenous conjugated estrogens (0.6 mg/kg) if they are given 4 to 5 days prior to surgery (104,111).

Furthermore, with reduced or absent renal function, these patients metabolize drugs such as antibiotics, anesthetics, and analgesics poorly. Drug administration in ESRD must be done judiciously with careful attention to the pharmacokinetics of particular drugs. Multiple guidelines exist that can direct drug dose reductions for patients with ESRD (112,113).

HEPATIC RISK ASSESSMENT

An increasing number of patients with chronic liver disease, advanced or end stage, will require non-liver transplant surgery (114). Reasons for this increase are; an aging population, better long-term survival of patients with liver cirrhosis, and continuously improving outcomes after surgery and critical care medicine (115). Historically, liver dysfunction was related to chronic viral or alcoholic hepatitis. While the incidence of these conditions has not changed dramatically in recent years, the rising rate of obesity has led to nonalcoholic fatty liver disease, which is increasingly recognized as the most common cause of chronic liver disease (CLD) in the United States (116).

As mentioned earlier, thorough preoperative evaluation of patients includes a comprehensive history and physical examination, with laboratory testing based upon historical and physical findings. Routine testing of liver function or coagulation in asymptomatic patients rarely yields abnormal results or changes in perioperative management (7). However, patients with history of liver disease, jaundice, blood transfusions, the use of alcohol or other recreational drugs, hepatitis, or physical findings of icterus, hepato-splenomegaly, palmar erythema, or spider nevi should be tested to rule out occult or active liver diseases (115).

Table 8.8 Child-Turcotte-Pugh (CTP) Classification of Liver Disease and Operative Mortality

Component	Score		
	1 Point	2 Points	3 Points
Ascites	None	Controlled with medication	Treatment-refractory
Encephalopathy	Absent	Grade I–II; Controlled with medication	Grade III–IV; treatment refractory
Albumin g/L	>3.5	2.8–3.5	<2.8
Bilirubin mg/dL	<2	2–3	>3
INR	<1.7	1.7–2.3	>2.3
CTP Classification	Class A (5–6 points)	Class B (7–9 points)	Class C (10–15 points)
90 day Mortality risk (abdominal surgery)	2%–10%	2%–30%	12%–76%

Source: Adapted from Hanje AJ, Patel T. Preoperative evaluation of patients with liver disease. *Nat Clin Pract Gastroenterol Hepatol.* 2007;4:266–276; Muir AJ. Surgical clearance for the patient with chronic liver disease. *Clin Liver Dis.* 2012;16:421–433; and Hoetzel A, Ryan H, Schmidt R. Anesthetic considerations for the patient with liver disease. *Curr Opin Anesthesiol.* 2012;25(3):340–347, with permission.

Patients with acute hepatitis (viral or alcohol-induced) should have their surgery delayed until the acute phase of the disease process has passed and liver function tests have returned to normal. Mortality rates among these patients can range from 10% to 58% if surgery is pursued. Patients with acute liver failure/fulminant liver failure, defined as the development of jaundice, coagulopathy, and hepatic encephalopathy within 26 weeks in a patient with acute liver injury and without pre existing liver disease, are critically ill, and all surgery other than liver transplantation is contraindicated in these patients (117). Contrarily, patients with chronic infectious hepatitis, which is stable, tolerate surgery with minimal mortality (114,118,119). Of course the operator should practice universal precautions with all surgical interventions, regardless of the patient's known infectivity status.

Assessing the severity of the underlying liver disease is important to determine perioperative outcome, and has been correlated to two classification systems; the Child-Turcotte-Pugh (CTP) classification and the model of end-stage liver disease (MELD) score. The Child-Turcotte score was the first predictor of surgical risk/mortality for patients undergoing surgical intervention; specifically, patients having portacaval shunts. The system was modified by Pugh and colleagues to include prothrombin time in place of the subjective assessment of nutritional status, for use in patients undergoing esophageal transections for bleeding varices (120,121). Although widely known for classifying liver disease, this system has been criticized for utilizing subjective variables (ascites and encephalopathy) in developing a score. However, the CTP score correlates with mortality in patients undergoing differing types of surgery (115,122) (Table 8.8). The MELD score was originally devised as a prognostic measure of short-term mortality in patients with cirrhosis undergoing placement of a transjugular intrahepatic porto-systemic shunt (TIPS) (123). The MELD score is derived from a complex formula which incorporates three biochemical variables (serum total bilirubin, serum creatinine, and the international normalized ratio [INR]) and assigns the patient a score of 8 to 40 (Table 8.9). The risk of morbidity and mortality in patients with liver disease depends upon the type of surgery and has been correlated to

Table 8.9 Model for End-stage Liver Disease (MELD) Score

$$\text{MELD Score} = (9.6 \times \log_e[\text{Creatinine}]) + (3.8 \times \log_e[\text{Bilirubin}]) + 11.2 \times \log_e[\text{INR}] + 6.4$$

Creatinine levels above 4.0 mg/dL, are assigned 4.0 mg/dL. Levels under 1.0 mg/dL are assigned 1.0 mg/dL. If the patient has had dialysis twice in the previous week, the value is assigned 4.0 mg/dL

Bilirubin levels below 1.0 mg/dL are assigned 1.0 mg/dL

INR levels below 1.0 are assigned 1.0

The maximum score is 40. Scores calculated greater than 40, are assigned a value of 40.

MELD Score	Less than 10	10–15	Greater than 15
	Low Risk	Intermediate Risk	1. High Risk
30 Day Mortality (Abdominal/cardiac/orthopedic surgery)	5%–5.7%	10%	2. >50%

Preoperative risk assessment for patients with liver disease. *Med Clin N. Am.* 2009;93:917–929, and Friedman LS. Surgery in the patient with liver disease. *Trans Am Clin Climatol Assoc.* 2010;121:192–204, with permission.

the aforementioned classification systems (Tables 8.8 and 8.9) (122). However it is likely that over the last two decades, mortality rates have decreased, despite the absence of large studies confirming this assumption (115).

Patients with cirrhosis of the liver also have coagulopathies, which need to be corrected prior to surgery. Vitamin K, fresh frozen plasma, or cryoprecipitate may be administered to correct the prothrombin time to within 3 seconds of normal. Figure 8.2 presents an algorithm for patients with liver disease facing surgery.

Finally, selection of medications in patients with hepatic dysfunction needs to be done carefully, from types of perioperative antibiotics to anesthetic agents and analgesics. Patients with liver dysfunction are particularly susceptible to anesthetic effects such as changes in hepatic metabolism of medications and changes in hepatic blood flow. Alterations of the type and the dose of an agent are necessary to avoid postoperative hepatic dysfunction and hepatitis. Postoperative pain management with narcotic agents needs to be reduced by as much as 50% to account for the altered hepatic metabolism in these patients (124).

PREOPERATIVE NUTRITIONAL ASSESSMENT

There is a clear correlation between degree of malnutrition and increased risk of perioperative complications in cancer patients undergoing surgery (125). The broader consideration of nutrition in the gynecologic cancer patient is discussed in Chapter 32. The intent of this section is to present the concepts of preoperative nutritional evaluation and support of the gynecologic oncology patient undergoing surgery. Early refeeding and enteral and parenteral nutritional support in the postoperative patient will be discussed later.

The incidence of malnutrition among cancer patients has been estimated to be 20% to 80%, with the prevalence among gynecologic oncology patients being approximately 20%. For example, ovarian cancer patients are 19 times more likely to have moderate malnutrition when compared to patients with other

gynecological malignancies or benign conditions (126,127). Among malnourished gynecologic oncology patients, patients have been found to have an increased risk of postoperative complications, longer lengths of stay, hospital readmissions, reoperations, earlier cancer recurrences, and residual tumor after initial surgery (127–129). The methods for assessing malnutrition has varied among investigators and has included weight loss over a given time, various objective anthropometric parameters (e.g., weight loss, body mass index, triceps skinfold thickness, and arm circumference), biochemical testing (e.g., serum albumin, prealbumin, total protein, transferrin, hemoglobin, and vitamins), and immunologic testing (skin sensitivity tests) (Table 8.10) (130).

Nutrition screening refers to the initial clinical evaluation that can quickly identify patients at high risk for malnutrition and who, later, may undergo a more formal and extensive nutritional assessment. Such instruments are the Malnutrition Screening Tool (MST) and the Malnutrition Universal Screening Tool (MUST), which have been used in oncology patients (Table 8.11). Logically, identifying patients at nutritional risk, by screening, will mark them for subsequent formal nutrition assessment, and identify opportunities for medical nutrition therapy, which ultimately should improve patient outcomes. Unfortunately, this sequence of assumptions has never been subjected to prospective confirmation in clinical trials (131).

Many nutrition assessment tools have been developed, including subjective and objective data to assign risk, and some have been validated in cancer patients, including gynecologic cancer patients. Those instruments that have been used in cancer patients

include the Subjective Global Assessment (SGA), the Patient-Generated Subjective Global Assessment (PG-SGA), Nutrition Risk Index (NRI), the Mini Nutritional Assessment (MNA), Prognostic Nutritional Index (PNI), and the Nutritional Risk Screening 2002 (NRS-2002) (Table 8.11). Although just examples

Table 8.10 Measurement of Nutritional Depletion

Parameters	Depletion		
	Mild	Moderate	Severe
Triceps skin fold (TSF) % Standard	50–90	30–50	<30
Mid-arm muscle circumference (MAMC) % Standard	80–90	70–80	<70
Albumin g/dL	3.0–3.4	2.1–3.0	<2.1
Total lymphocyte count (TLC) Cmm	1200–1500	800–1200	<800
Weight loss, % initial			
In 1 week	<1	1–2	>2
In 1 month	<2	2–5	>5
In 3 months	<5	5.0–7.5	>7.5
In 6 months	<7.5	7.5–10.0	>10.0

Table 8.11 Nutritional Screening and Assessment Tools

Tool	Components
Screening Instruments	
Malnutrition Screening Tool (MST)	3 items: weight, percentage weight loss, appetite
Malnutrition Universal Screening Tool (MUST)	3 items: BMI, percentage weight loss, acute disease effect
Nutritional Risk Screening 2002 (NRS-2002)	4 items: reduced BMI, percentage weight loss, decreased dietary intake, acute disease effect
Assessment Instruments	
Patient-Generated Subjective Global Assessment (PG-SGA)	Patient (4 questions): weight history, symptoms, food intake, activity level Health care provider: metabolic demand, diagnosis and comorbidities, physical examination
Subjective Global Assessment (SGA)	History and physical examination to assign nutrition score
Prognostic Nutritional Index (PNI)	Equation: PNI Score (%) = $158 - 16.6$ (albumin level in gm/dL) $- 0.78$ (triceps skin fold in mm) $- 0.2$ (transferrin level in mg/dL) $- 5.8$ (Grade of delayed hypersensitivity)
Nutrition Risk Index (NRI)	Equation: $NRI = 1.519$ (serum albumin; g/dL) $+ 41.7$ (current weight/usual weight) $\times 100$
Mini Nutritional Assessment (MNA)	18 items: Screening portion (6 questions): food intake, weight loss, mobility stress, BMI; Assessment (12 questions): medical history, eating habits, anthropometric measurements

Source: Adapted from Huhmann MB and August DA: Reivew of American Society for Parenteral and Enteral Nutrition (ASPEN) clinical guidelines for nutrition support in cancer patients: nutrition screening and assessment. *Nutr Clin Pract.* 2008;23:182–188, with permission.

of the many assessment tools available, none has emerged as the “gold standard” for nutritional screening and/or nutritional assessment among cancer patients, and their use depends upon which organization endorses a particular tool.

The SGA tool, originally described by Detsky in 1987, uses history and physical examination to assign a nutrition risk score. The PG-SGA was adapted from the SGA by Ottery, and later modified by McCallum and Polisen to give a numerical score of 0 to 47, specifically for the oncology population (132–135). It consists of two sections, one of which is done by the patient. This portion elicits information related to weight history, symptoms, food intake, and activity level. The other section, completed by a health care professional, includes an evaluation of metabolic demand, diagnosis, and comorbidities in relation to nutrition requirements and elements of physical examination. Every portion of the tool is given a numeric score, including the patient's portion, which is used to triage intervention. Laky and colleagues in 2007 showed, in a prospective fashion, that the PG-SGA could be easily administered to identify gynecological cancer patients at risk for malnutrition. Their work established a prevalence of malnutrition among their patients in Brisbane, Australia. Among 145 patients with known or suspected gynecologic cancer, 116 patients were classified as well nourished (PG-SGA A), 29 patients were moderately malnourished (PG-SGA B), and none of the patients were severely malnourished (PD-SGA C). These investigators found that ovarian cancer patients were 19 times more likely to be

malnourished, compared to patients with other gynecologic malignancies or benign conditions. In addition, they found that preoperative serum albumin levels correlated with the PG-SGA B score among ovarian cancer patients, similar to other previous reports (128,129,135), and may be a good indicator of malnutrition among gynecologic cancer patients in the absence of a full nutritional assessment (126). In 2008, Laky found that the scored PG-SGA, albumin level, triceps skinfold thickness, and total-body potassium could predict the SGA better than chance. The authors concluded that the scored PG-SGA is the most appropriate tool for identifying malnutrition in gynecologic cancer patients.

The NRI was used to stratify nutrition risk in the Veterans Affairs Total Parenteral Nutrition Cooperative Study Group trial of perioperative parenteral nutrition. It is a simple equation that uses albumin and weight to classify individuals as either well nourished or malnourished. The equation:

$$NRI = 1.519 (\text{serum albumin; g/dL}) + 41.7 (\text{current weight/usual weight}) \times 100$$

A score less than 100 is considered malnourished (31). This particular tool has not been studied in gynecologic oncology patients.

The MNA is an 18-item tool that is divided into two sections: screening and assessment. The screening segment contains 6 questions related to food intake, weight loss, mobility, stress, and body mass index. If this score is 11 or less, then a health care provider will complete the remaining 12-item assessment. A total score of <17 indicates malnutrition and a score between 17 and 23.5 indicates risk for malnutrition. This instrument has been validated in the elderly population, but its use among cancer patients is limited and nonexistent among gynecologic cancer patients.

The PNI is an objective evaluation of nutritional status which includes anthropometric measurements and laboratory testing and an assessment of cell mediated immunity by testing to mumps, tuberculin and *Candida* (the grade of response is 0 nonreactive; 1 <5 mm induration; 2 ≥5 mm induration) (136). The information gathered is put into the formula below:

$$\begin{aligned} \text{PNI Score (\%)} = & 158 - 16.6 (\text{albumin level in g/dL}) - \\ & 0.78 (\text{triceps skin fold in mm}) - \\ & 0.2 (\text{transferrin level in mg/dL}) - \\ & 5.8 (\text{Grade of delayed hypersensitivity}) \end{aligned}$$

If the PNI is <40%, then the patient is determined to have normal nutritional status; PNI 40% to 49% indicates mild malnutrition; PNI >50% is severe malnutrition. Santoso et al. compared this objective, yet cumbersome and expensive, method to the SGA for gynecologic malignancies. They found that agreement between the two methods was only fair to moderate, with the SGA methodology trending toward underreporting when compared to the objective method (137).

The NRS 2002 was developed to include measures of current malnutrition and disease severity. This scoring system assesses current malnutrition by scoring the amount and duration of weight loss, reduced BMI, and recent decrease in dietary intake. In addition, the severity of illness is graded as a reflection of increased nutritional requirements. A score is calculated for each part of the assessment and added together for the final score. A score ≥3 indicates the need to start nutritional support. This NRS 2002 is recommended by the European Society for Clinical Nutrition and Metabolism (ESPEN) for the screening of hospitalized patients and has been widely accepted in Europe. It is important to note that this tool is useful in identifying patients who will benefit from nutrition intervention, but does not categorize the risk of malnutrition. This tool has not been evaluated among patients with gynecological malignancies undergoing surgery (138).

Currently, the American Society of Parenteral and Enteral Nutrition (ASPEN) and the European Society for Clinical Nutrition and Metabolism (ESPEN) do not recommend routine nutrition support therapy (NST-parenteral or enteral) in

patients undergoing major cancer operations. The risks and costs of routine perioperative NST outweigh benefits in terms of surgical outcomes in cancer patients (125,138).

Several RCTs have been done to evaluate NST in cancer patients undergoing surgery. The largest trial, the Veterans Affairs Cooperative Study, randomized 395 surgical (abdominal or noncardiac thoracic surgeries) patients, mostly male, to receive at least 7 days of preoperative and 3 days of postoperative TPN or to receive no perioperative nutritional supplementation. The TPN group had a greater number of infectious complications, mostly among patients classified as borderline or mildly malnourished compared to the unfed patients (14.1% vs. 6.4%). However, a subset of severely malnourished patients derived benefit from lower operative complication rates (5% vs. 43%, $p = 0.03$) without incurring an increase in infectious complications. The overall 30- and 90-day mortality rates were not different between the groups (31). Meijerink et al. completed a trial of preoperative nutrition among 151 patients undergoing surgery for gastric or colorectal cancer and randomized to preoperative TPN versus enteral nutrition (EN) versus standard oral diet (SOD). The authors found that there was no difference in mortality among the groups. However, patients who were severely malnourished and received either TPN or EN had fewer intra-abdominal abscesses than the MOD, but there was a difference in infectious morbidity between the TPN and EN groups (140). A similar study by Bozzetti et al. randomized severely malnourished patients undergoing resection of gastric or colonic malignancies to 10 days of preoperative and 9 days of postoperative TPN or SOD with hypocaloric TPN postoperatively only. The TPN only group showed lower noninfectious postoperative complication rates and mortality (141). And finally Wu et al. randomized 468 patients to pre- and postoperative TPN/EN versus postoperative hypocaloric PN among moderately to severely malnourished patients undergoing surgery for gastrointestinal cancers. The investigators found fewer complications, lower mortality, and shorter lengths of stay among the full nutrition support group (142). Because of the findings of these trials, ASPEN and ESPEN suggest that perioperative NST may be beneficial in moderately or severely malnourished patients if administered for 7 to 14 days preoperatively. The potential benefits of NST must be weighed against the potential risks of the NST itself and of delaying the operation. The authors direct the reader to reviews of these recommendations, which have been done by Huhman and August (for ASPEN) (125) and Braga et al. (for ESPEN) (139).

PREPARATION FOR SURGERY

Medication Management

In preparation for surgery, patients may need to decrease or stop taking certain medications, especially those associated with higher incidence of anti-coagulation risks. Appropriate notice and clear instructions should be given to patients in this case, as some medications require several days of cessation to produce desired results. It will take approximately 4 days after warfarin therapy is discontinued for the international normalized ratio (INR) to reach 1.5 for those patients with INR levels between 2.0 and 3.0. Many patients on warfarin do not need to be covered with heparin therapy preoperatively. Administration of treatment-dose intravenous heparin or low-molecular-weight heparin (LMWH) while the INR is subtherapeutic is recommended for patients with a history of mechanical mitral valve, ball and cage valve, acute venous, or arterial thromboembolism within 3 months of surgery, or atrial fibrillation with a history of thromboembolic stroke (143). A thorough discussion pertaining to usage of over-the-counter medications and herbal supplements

is crucial in presurgery medication management. Patients should be counseled on the use of nonprescription medications, such as aspirin, nonsteroidal anti-inflammatories, ginkgo biloba, saw palmetto, garlic, ginseng, and vitamin E, as they have antiplatelet components and may enhance bleeding risk (144, 145). If possible, anemia should be corrected preoperatively. The use of recombinant human erythropoietin with concurrent iron and folic acid supplementation 2 to 3 weeks preoperatively has been shown to reduce allogeneic blood transfusions in patients undergoing elective surgery (146). It has been estimated that 60% of all blood transfused in the United States is given to surgical patients.

Numerous studies have shown the benefit of starting medications, such as statins and β -blockers, in the preoperative setting to reduce cardiac risk (147). The perioperative use of β -blockers has been shown to reduce the incidence of postoperative myocardial ischemia, myocardial infarction, and cardiac mortality by decreasing myocardial oxygen consumption and workload, although this has not been studied specifically in the morbidly obese population (147). Current ACC/AHA guidelines recommend that β -blockers should be continued in patients undergoing surgery who are receiving β -blockers to treat angina, symptomatic arrhythmias, hypertension, or other ACC/AHA class I guideline indications (148). For high-risk patients not receiving β -blockade, therapy should start before elective surgery, with the dose titrated to achieve a heart rate at rest of 50 to 60 beats/minute (149). The perioperative use of β -blockers in high-risk patients undergoing major noncardiac surgery is supported by the published data. However, studies have questioned the benefits of this approach in moderate-risk patients and report that the potential harm in low-risk groups might outweigh the benefit, stressing the importance of patient selection (150).

Statins have also been shown to be effective cardioprotective drugs in the perioperative setting (147). Statins have been shown to act as plaque stabilizers and therefore possibly decrease the risk of thromboembolic events (147,151). With their low side effect profile and well-documented benefits, statins should be strongly considered for all obese patients with elevated serum cholesterol or triglycerides (152).

Close to 2 million patients undergo coronary angioplasty each year in western countries, and >90% of these patients will have coronary stents placed as part of their intervention (153,154). Patients with bare metal stents are normally taking low-dose aspirin 81 mg. It is recommended that they stop taking aspirin 7 days before surgery (155,156).

Patients with drug-eluting stents take oral aspirin 81 mg, or even aspirin 325 mg, and, for the first 12 months after stent placement, daily oral clopidogrel 75 mg (156,157). Ideally, these patients should not undergo elective surgery, within the first 12 months after stenting. After the first 12 months, both medications are recommended to be stopped 7 days before surgery to reduce the risk of intra- and postoperative bleeding (155).

It is not uncommon for gynecologic oncology patients to undergo neoadjuvant chemotherapy. Most gynecologic oncologists would agree that the timing of surgery in relation to chemotherapy is crucial. In most cases, the surgical intervention should replace a cycle of chemotherapy. With regard to bevacizumab, special considerations should be taken into account since there is the added risk of bowel perforation and poor wound healing. The incidence, type, and timing of postsurgical bleeding events and wound-healing complications were assessed in surgical patients in the AVastin And DOcetaxel (AVADO) and Avastin THERapy for advaNced breAst cancer (ATHENA) trials. Both study protocols followed recommendations to withhold bevacizumab for at least 6 weeks before elective surgery, and to wait 28 days (or until the wound was fully healed) after major surgery before recommencing bevacizumab therapy (158). Another study by Erinjeri et al. investigated how the timing of administration of bevacizumab affected the risk of wound healing in patients undergoing chest-wall port placement. They concluded the risk

of a wound dehiscence requiring a chest wall port explant in patients treated with bevacizumab was inversely proportional to the interval between bevacizumab administration and port placement, with significantly higher risk seen when the interval is less than 14 days (159). Scappaticci et al. assessed postoperative wound healing complications in two randomized trials of 5 mg/kg bevacizumab in colorectal cancer treatment. Bevacizumab administered in combination with 5-fluorouracil/leucovorin-based chemotherapy 28 to 60 days after primary cancer surgery caused no increased risk of wound healing complications compared with chemotherapy alone. While wound healing complications were increased in patients who had major surgery during bevacizumab therapy, the majority of bevacizumab-treated patients experienced no complications (160).

Blood Banking

Patients and their families are taking a more proactive role in their health care and thereby are entering into surgeries knowledgeable of risks and expecting alternative options. Preoperative counseling should include discussion of the potential for blood transfusions and associated risks. Transfusion rates of approximately 5% have been reported for patients undergoing abdominal hysterectomy for benign disease (160,161). Radical procedures performed for the treatment of gynecologic malignancies are associated with an estimated blood loss of 1,000 mL or greater. Transfusion rates for patients undergoing radical hysterectomy have been reported as high as 80% (162), but rates of 10% to 20% are more typical in the recent literature. The risk of transfusion-transmitted infection of human immunodeficiency virus, hepatitis B virus, and hepatitis C virus from red blood cell transfusion is estimated at 1:2.1 million units, 1:250,000 units, and 1:1.9 million units, respectively (163). Although these rates have significantly decreased in the last decade with the introduction of new screening technologies, transmission of other agents, bacterial contamination, transfusion reactions, increased infection complications, and immunosuppression remain risks of allogeneic blood transfusion (164,165). One alternative both physicians and patients have turned to is the use of donor blood in the perioperative period.

Since the mid-1980s, preoperative autologous blood donation (PABD) has been utilized in order to avoid allogeneic blood transfusion in patients undergoing elective surgery where excessive blood loss is anticipated. Although this practice decreases homologous blood use, 15% of autologous donors will still receive allogeneic transfusions, and 50% of units collected are not used and must be discarded (166). Furthermore, PABD greatly increases the likelihood of any transfusion being necessary and is not without medical risks. Severe reactions during autologous donation occurred at a rate of 0.32% per unit collected and 0.75% per donor. Serious incidents during blood collection that required hospitalization were 12 times more likely in PABD compared to allogeneic donors (167). Transfusions to the wrong recipient, bacterial contamination, febrile nonhemolytic reactions, and allergic reactions have also been reported with autologous transfusion. The cost-effectiveness of PABD has been found to be extremely poor and has steadily deteriorated over the decade (166–169).

Acute normovolemic hemodilution (ANH) is an autologous blood-procurement strategy that is equivalent to PABD in reducing allogeneic transfusion needs. Its clinical utility has been extensively studied in patients undergoing radical prostatectomy, total joint replacement, and, more recently, major colorectal surgery. During ANH, blood is procured in the holding or operating room and replaced simultaneously with colloid and crystalloid until a target hematocrit level of 28% is reached or blood volume of 1,500 mL is removed (170). The patient's blood becomes diluted and the amount of actual red cell mass lost

during surgery is reduced. ANH obviates the costs of blood testing, storage, or wastage because all blood collected during ANH is kept in the operating room and returned to the patient before the end of surgery. It is simple to perform and more convenient for the patient. Since the blood is collected at point-of-care there is no possibility for clerical error or contamination. ANH has been shown to be a cost-effective yet underutilized strategy to reduce allogeneic blood transfusions (170–172). ANH in which the blood is kept in a continuous circuit with the patient is often a workable alternative for a Jehovah's Witness patient (170,173).

The utilization of erythropoietin in oncology patients should on a case by case basis due to recent evidence of adverse effects in oncology patients (174).

Bowel Preparation

It is generally accepted that full mechanical bowel preparation is indicated when intestinal injury or bowel resection is anticipated. Mechanical bowel cleansing is considered to be a crucial factor in preventing postoperative infectious complications and disruption of bowel anastomosis. In addition to the decreased risk of infection, mechanical bowel preparation has several advantages. It facilitates palpation of the entire colon during laparotomy. It may decrease operative time by enabling the surgeon to work with a clean bowel and improve handling during bowel anastomosis or repair. Furthermore, removal of solid material from the gastrointestinal tract prior to laparoscopy may improve exposure and lessen the chance of injury secondary to manipulation of a heavy and distended feces-laden colon with the relatively traumatic laparoscopic grasping instruments.

Historically, clearing the colon in preparation for surgery was a complicated procedure requiring several days of clear liquid diet, cathartics, enemas, and preoperative hospitalization. The introduction of polyethylene glycol (PEG) electrolyte solution in the early 1980s revolutionized bowel preparation (175). PEG is an iso-osmotic solution with uniquely designed electrolyte concentrations that result in virtually no net absorption of ions or water, and large volumes can be administered without significant fluid or electrolyte alterations. Several randomized studies have demonstrated that bowel cleansing with PEG can be performed safely as an outpatient preparation prior to colorectal surgery without increasing complication rates (176). Although effective, bowel preparation with PEG has some disadvantages related to patient tolerance and compliance. It requires oral intake of 4 L of a salty-tasting solution over a relatively short period of time. Many patients experience nausea, vomiting, and abdominal bloating and discomfort, and are unable to drink the required volume.

Sodium phosphate is an osmotic cathartic that provides quality bowel cleansing while avoiding the need to ingest a large volume of solution (177,178). Generally, a 45-mL dose (or two doses taken 4 hours apart) is taken with at least four glasses of clear liquid with each dose. Colonic cleansing with this method may cause intravascular volume contraction in some patients. A randomized, blinded study showed that rehydration with a carbohydrate-electrolyte "sport" drink resulted in significantly less intravascular volume contraction as compared to rehydration with water (179). A meta-analysis of 8 blinded studies that compared sodium phosphate to PEG for colonoscopy preparation suggests that sodium phosphate is an effective, better tolerated, and less costly regimen (180). Comparisons between these 2 preparations have also been studied in patients undergoing colorectal surgery, with similar results (178,181). Contraindications for the use of sodium phosphate include patients with renal insufficiency, symptomatic CHF, and liver failure with ascites (182). Hyperphosphatemia, hypernatremia, hypocalcemia, and hypokalemia have been reported after bowel preparation with sodium phosphate, but generally without clinical

significance (177,178,180,183). However, serious and fatal metabolic derangements have been reported, and caution should be used in elderly patients or when prescribing multiple dose regimens (182–185). The FDA suggests obtaining posttreatment laboratory evaluation (basic metabolic panel, calcium, phosphate), especially if more than 45 mL is taken in a 24-hour period (182). Low-volume bowel preps are now available, such as Suprep (sodium sulfate, potassium sulfate, and magnesium sulfate). Generally, the risk of electrolyte abnormalities are lower with these newer preps; however, posttreatment laboratory evaluation should be considered (186).

Although regarded as being essential in preventing complications of colorectal surgery, the necessity of mechanical bowel cleansing has been strongly disputed for the past 15 years. The claims that preoperative mechanical bowel preparation reduces anastomotic leakage and SSI are based on observational studies and expert clinical experience. Since 1992, several prospective randomized trials reported that elective colon and rectal surgery may be performed safely without mechanical bowel preparation. All patients in these trials received systemic antibiotics. However, the majority of these trials were greatly underpowered, with a 60% or greater chance that a type II error occurred (187,188). In 2006, Bucher et al. published a meta-analysis of 1,297 patients from 7 randomized, controlled trials and concluded that mechanical bowel preparation does not reduce the incidence of infectious complications and may be harmful with respect to leakage at the anastomosis (189). Another meta-analysis of 1,592 patients (9 trials) came to the same conclusions and stated that the dogma that mechanical bowel preparation is necessary before elective colorectal surgery should be reconsidered (190). In a survey of members of the American Society of Colon and Rectal Surgeons, essentially all routinely used mechanical bowel preparation, although 10% questioned its importance. Of the 515 surgeons who responded to the questionnaire, 47% routinely used sodium phosphate, 32% routinely used PEG, and 14% alternated between the 2 agents (191).

The importance of appropriate intravenous antimicrobial prophylaxis in patients undergoing colorectal surgery is well established and was discussed earlier in this chapter. There are conflicting opinions and data regarding whether preoperative oral antibiotics as part of a bowel preparation add any additional benefit for reduction of SSI (192,193). Although there are still strong proponents of this practice (194), oral antibiotic usage with preoperative mechanical bowel cleansing is declining (191).

Infection Prophylaxis

The use of prophylactic antimicrobials plays a large role in reducing the rates of surgical site infections (SSIs) and should be used in clean or clean-contaminated operations, which include most procedures performed by gynecologic oncologists. Radical pelvic surgery introduces women to a higher risk of postoperative infection secondary to several potential factors: lengthened operating time, average of age of patient requiring this specific surgery, increased blood loss, anemia, potential hypothermia, probable poor nutritional status, the presence of tumor, prior pelvic irradiation, diabetes, obesity, peripheral vascular disease, and a history of postsurgical infection (195,196). Prophylactic antibiotics should provide coverage consistent with the microbial milieu most likely to be encountered. In gynecologic oncology surgery, the most common infecting organisms are coliforms, enterococci, streptococci, clostridia, and bacteroides.

Several guidelines for antibiotic prophylaxis in surgery have been published (195,197,199,200). Most reports recommend cefazolin for gynecologic procedures. Although no longer available, cefotetan had been the preferred antibiotic for prophylaxis in longer radical gynecologic operations, as well as for

prophylaxis prior to colorectal surgery, due to longer half-life and broad spectrum coverage (198). An appropriate alternative for surgical procedures with a higher chance of bowel resection or injury is cefazolin plus metronidazole or ampicillin-sulbactam (200). Cefoxitin is another option, but availability has been limited. Most patients with a penicillin allergy can be treated with cefazolin; however, when allergy prohibits the administration of a cephalosporin, alternative regimens are clindamycin with gentamicin, a fluoroquinolone, or aztreonam (197). Itani et al. reported on a randomized, double-blinded trial in patients undergoing elective colorectal surgery that suggested ertapenem as an effective alternative to cefotetan (201). Ertapenem has received FDA approval for prophylaxis for elective colon resection; however, the 2006 Medical Letter guidelines caution against the routine use of ertapenem for surgical prophylaxis due to cost and concerns that this practice may result in increased rates of antibiotic resistance (200).

When considering dosing orders to achieve and maintain effective tissue levels, parenteral antibiotics should be given within 1 hour (between 1 and 2 hours for fluoroquinolones and vancomycin) prior to skin incision as a loading dose (197). For patients weighing >70 kg, the dosage should be doubled (i.e., cefazolin 2 g intravenously [IV]) or weight-based dosing should be used. Repeat doses should be given intraoperatively for surgeries lasting longer than 3 to 4 hours or when blood loss exceeds 1,000 mL (198,200). Guidelines from the National Surgical Site Infection Project recommend that prophylactic antibiotic use for abdominal or vaginal procedures end within 24 hours of the operation (197). The majority of the published evidence supports the use of an appropriately timed administration of a single dose of antibiotic and indicates that repeat doses postoperatively are unnecessary and subject the patient to the potential emergence of resistant organisms (195,197,198,200).

The American College of Surgeons and the National Surgical Quality Improvement Plan employ a prospective, peer-reviewed database to quantify 30-day risk-adjusted surgical outcomes that encompass such variables as preoperative risk factors and postoperative mortality and morbidity, allowing comparison of outcomes among all hospitals in the program. Enrolled hospitals abstract case data into the database, the data are quantified, and the database generates comprehensive semiannual reports to the hospitals as well as real-time, continuously updated, online benchmarking reports (202).

Surgical site infections account for nearly 40% of nosocomial infections in surgical patients and occur in up to 20% of patients undergoing abdominal surgery (195,197). They are a significant source of postoperative morbidity, resulting in longer hospital stays, increased rates of intensive care unit admissions, hospital readmissions, and subsequently increased costs. Mortality rates increase 2 to 3 times for patients with an SSI as compared to patients who do not develop an SSI (203,204). In addition to the administration of preoperative antimicrobial prophylaxis, preoperative skin preparation is used to reduce the risk of SSI by decreasing the microbial count at the projected site of incision. A meta-analysis of 6 trials concluded that although whole-body scrubs or showers with antiseptic agents such as chlorhexidine or povidone-iodine prior to surgery reduce bacterial counts on the skin, this practice did not reduce wound infection rates (205). Surgical infection occurrences are noted to be influenced by both patient and operative environmental factors. Therefore, patients undergoing surgery should be instructed to bathe or shower normally the night or morning prior to surgery, removing any debris from the skin surface and decreasing environmental contaminants.

Inappropriate hair removal techniques can traumatize the skin and provide an opportunity for colonization of microorganisms. There is no evidence that hair removal prior to surgery will prevent or reduce SSI. To the contrary, meta-analysis evaluating hair removal techniques demonstrated a twofold increase in SSI when patients underwent hair removal by shaving versus clipping

(206). Hair is generally sterile and therefore does not need to be removed unless the hair around the incision will interfere with the operation. When hair removal is necessary, the simplest and least irritating method of hair removal is an electric or battery-powered clipper with a disposable head (195,206). Some infection control experts advocate removing all razors from hospitals and operating rooms (207).

Special Considerations for Obese Patients

A heightened awareness of potential comorbidities should be extended when preparing morbidly obese patients for surgery. Coexisting disorders, such as coronary artery disease, hypertension, obesity-hypoventilation syndrome, obstructive sleep apnea, adult-onset diabetes mellitus, pulmonary hypertension, gastroesophageal reflux, impaired cardiac function, and hypercoagulability are common in morbidly obese patients and may be undiagnosed at the time of surgery. Certain symptoms of such comorbidities may not manifest themselves until the patient undergoes physiologic stress related to surgery and thereby contribute to increased perioperative morbidity and mortality. For example, baseline pulmonary function studies of markedly obese patients demonstrate mild hypoxemia; decreased vital capacity, tidal volume, and expiratory reserve volume; increased resistance; and ventilation-perfusion inequalities (208). During the postoperative period, severe hypoxemia may occur secondary to sedation, pain, immobility, atelectasis, and anemia, leading to cardiac arrhythmia or ischemia. A thorough preoperative medical history and physical examination should be performed to increase the findings of coexisting disease and minimize surgical risk. A comprehensive review of the pathophysiology associated with morbid obesity is beyond the scope of this chapter, and we direct the reader elsewhere for a thorough review (209).

Surgery in morbidly obese patients poses many challenges for teams on both sides of the surgical drape. The primary concern of the anesthesiologist is gaining adequate control of the airway. The combined problems of increased aspiration risk, rapid oxygen desaturation caused by decreased functional residual capacity, baseline hypoxemia, and increased oxygen demand, in addition to technical difficulties due to anatomic fat deposits, make intubation a high-risk procedure. An awake, fiberoptic-assisted intubation is often the technique of choice for obtaining an airway. Extubation should be delayed until the patient is fully awake and ideally sitting upright (210). There are technical operating room and instrumentation issues, which need to be addressed as well. Standard operating tables, stretchers, and hospital beds have weight limits, which have prompted specifically designed wider and sturdier models for the obese patient. Staff and patient safety during transfer of the patient from the operating table to the bed or gurney is also a concern in the extremely obese patient and must be taken into consideration. Proper retractors and extra-long instruments are essential and may not be available in all hospitals. Although these practical considerations are ostensibly mundane, failure to prepare will obviate a successful outcome, add frustration to all involved, and possibly put the patient at risk.

Recent reports in the gynecologic oncology literature suggest performing panniculectomy to improve exposure of the peritoneal cavity and pelvic structures (211–213). Although this is a relatively straightforward procedure, it does require some experience and planning for optimal results. Hospital credentialing of surgical privileges may require the involvement of a plastic surgeon or proctoring until proficiency is demonstrated. In addition, since panniculectomy is considered a cosmetic procedure, many insurers may require prior authorization with documentation of medical necessity, or they may deny any reimbursement.

CRITICAL CARE AND POSTOPERATIVE MANAGEMENT

Cardiovascular Issues

Monitoring Issues

There are many tools at the hands of the modern-day clinician when it comes to monitoring the cardiovascular function of the patient. Clinical examination, heart rate, blood pressure, and ECG are a few. In the critical care setting, the addition of the arterial catheter, central venous pressure, and pulmonary artery catheter increases sophistication. Most patients in the ICU can be managed with simple clinical parameters. Fluid status can be assessed by daily weights, pulse rate, blood pressure, and urine output. Continuous ECG monitoring is helpful for detecting arrhythmias and ischemia. Central venous pressure (CVP) is often used for assessment of volume status and a crude estimation of cardiac function. If a patient has a central line, then a port can be continuously transduced for CVP. It is a common mistake among novices to evaluate a single reading of CVP rather than reviewing the trend. When the CVP is correlated with volume status, the resulting graph is a scatter graph (i.e., no correlation). There is correlation only over time and in response to fluid challenges, transfusion, or therapy. One must remember that the CVP is a pressure measurement and not the desired measurement of volume (preload). Therefore, only crude estimations of fluid status can be made. When the status of a patient's cardiac output or fluid state is unclear, a minimally invasive hemodynamic monitor or an invasive pulmonary artery (PA) catheter (e.g., Swan-Ganz catheter) may be helpful. A minimally invasive hemodynamic monitor connects to an existing arterial catheter and performs continuous self-calibration. The sensor provides information on stroke volume, stroke volume variation, and cardiac output (214).

Pulmonary artery catheters are placed via a central vein (subclavian or jugular) as a central line. The catheter has a balloon-tipped transducer and is "floated" into the pulmonary artery. Waveforms of the right ventricle, pulmonary artery, and pulmonary capillary wedge pressure (PCWP) are directly visualized as the catheter progresses through the heart (Fig. 8.3), and confirmed placement is verified by chest radiograph (Fig. 8.4). Complications of placement include pneumothorax, arrhythmia, line sepsis (2%), and rarely, pulmonary artery rupture. The PA catheter allows the measurement of cardiac output and oxygen delivery and estimation of preload by obtaining the pulmonary artery occlusive pressure (PAOP) or PCWP, the "wedge."

A number of formulas for calculation of hemodynamic parameters are crucial in utilizing the PA catheter for the care of the critically ill patient (Table 8.12). Assessment of preload is desirable for determining fluid administration or diuretic requirements for patients. The ideal measure of preload would be left ventricular end-diastolic volume; however, since this is unobtainable with current technology, intensivists settle for "the wedge" as an estimation. By inflating the balloon placed in the pulmonary artery, a direct column of standing fluid exists between the left atrium, through the pulmonary vasculature, and back to the balloon (transducer). The PAOP can be measured and is a crude reflection of left atrial pressure. If the PAOP is elevated, the preload is adequate (or excessive), and if it is low, the patient may be volume depleted. These measurements, as previously mentioned with CVP, are dynamic and trend is important. For example, if the PAOP is low and a fluid bolus is given, the PAOP should increase if the diagnosis of volume depletion was correct.

Thermodilution techniques are used to calculate cardiac output by injecting saline via a proximal port in the PA catheter and measuring the thermal changes at the distal tip of the PA catheter. By combining the preload assessment provided by the

FIGURE 8.3. Pulmonary artery catheter wave-form readings as the catheter passes through the heart into the pulmonary artery. Y-axis is reading in millimeters of mercury (mm Hg).

PAOP and the calculated cardiac output, differentiation between volume depletion and cardiogenic disease states can be made (see section on shock). Newer PA catheters have been developed that can calculate right ventricular ejection fraction.

By taking a blood sample from the tip of the PA catheter, the most desaturated blood in the body is retrieved. In normal circulation, the blood from the superior vena cava and the inferior vena cava mix, and the blood from the coronary sinus is

added to give a sample known as the mixed venous blood. By evaluating the oxygen saturation of this blood, oxygen delivery can be calculated (Table 8.12). This measurement is perhaps the most important function of the PA catheter, and current technology allows this function to be continuous via an infrared sensor at the tip of the PA catheter. For example, if oxygen delivery is determined to be low, there are only 3 situations that the clinician can influence: increase cardiac output (with fluid, chronotropes, or inotropes), increase the hemoglobin, or increase the oxygen saturation. In a patient with a major operation and medical comorbidities, the measurement of a normal oxygen delivery provides reassurance to the clinician that end organs are being perfused.

FIGURE 8.4. Chest radiograph showing proper placement of pulmonary artery catheter in the pulmonary artery (arrow shows tip of pulmonary catheter).

Table 8.12 Hemodynamic formulas

Cardiac output (CO) = stroke volume (SV) $\times$ heart rate (HR) [4–8 L/min]

Cardiac index (CI) = CO/body surface area (BSA)

Systemic vascular resistance (SVR) = $\frac{\text{Mean arterial pressure (MAP)} - \text{Central venous pressure (CVP)}}{\text{CO}} \times 80$ [800–1200 dyne/s/cm²/m²]

Arterial O₂ content (CaO₂) = (1.36) (hemoglobin) (oxygen saturation) + 0.003 (partial pressure of oxygen) [20 mL O₂/dL]

O₂ delivery (DO₂) = CO $\times$ CaO₂ $\times$ 10 [600–1000 mL O₂/min]

O₂ availability (O₂AVI) = CI $\times$ CaO₂ $\times$ 10 [500–600 mL/min/m²]

O₂ extraction ratio = $\frac{(\text{CaO}_2 - \text{CvO}_2)}{\text{CaO}_2} \times 100$ [25%]

Values in brackets are normal values.

Calculation of the systemic vascular resistance (SVR) is also possible with a PA catheter. Because the SVR is a calculated value and not directly measured, inaccuracies are inherent and overinterpretation of this value is cautioned. Rather than relying on the calculated SVR, the clinician should have complete understanding of the measured blood pressure and cardiac output and the ramifications therein to make therapeutic decisions (SVR combines the 2 previously mentioned measured variables).

In one study of ovarian cancer patients undergoing cytoreductive surgery, 18% of patients had indications for PA catheter use (214). Because of the issues of volume status in these patients, PA catheter placement for postoperative fluid management may be especially helpful.

Acute Postoperative Myocardial Infarction

MI usually manifests with acute chest discomfort, elevated cardiac enzymes (troponin, creatinine phosphokinase [CPK], etc.), and ECG changes. Dyspnea, diaphoresis, nausea, and anxiety may also be associated. Risk factors that increase mortality from postoperative MI include female gender, advanced age, tachycardia, hypotension, and CHF (215,216). Treatment includes ICU monitoring with continuous ECG monitoring, supplemental oxygen, immediate oral aspirin 325 mg administration, sublingual nitroglycerin, and morphine sulfate as needed until pain resolves. β -blockers have been shown to decrease mortality by decreasing fatal arrhythmias and they are also part of the early treatment regimen. An evaluation for heparin therapy or thrombolytics can be made in consultation with a cardiologist.

Congestive Heart Failure

Patients with known CHF will be risk stratified, as previously mentioned, before major elective surgery. However, in the postoperative setting, CHF will present in a number of ways (165). Patients with CHF are in a continuous hypervolemic state, and issues of fluid balance (strict “ins” and “outs”) will be paramount during the perioperative period. In difficult cases, insertion of a PA catheter can be very helpful. Judicious fluid administration guided by the PAOP as well as selective use of inotropic support for augmentation of the cardiac output will aid the clinician in a successful outcome in these difficult patients (217).

Inotropes and Vasopressors

A variety of hemodynamically active drugs is available to support the cardiovascular function of patients in the perioperative period (218). In the broadest sense, these drugs can be categorized as vasopressors, which elevate blood pressure, and inotropes, which enhance cardiac output (219). When faced with a patient in whom oxygen delivery is low and an increase in cardiac output is desired, inotropes such as dopamine or dobutamine should be used. Dopamine, at lower doses, activates dopaminergic receptors and increases circulation in mesenteric, cerebral, and renal vascular beds. At intermediate doses, dopamine stimulates β -receptors in the heart and peripheral circulation. This activation causes tachycardia, increased stroke volume, and increased cardiac output. Increasing cardiac output in this fashion also increases demands for myocardial oxygen and could precipitate angina or MI (220). At high doses, dopamine acts as an α -agonist, causing vasoconstriction. Dobutamine is a β -1 agonist with much greater inotropic effect than dopamine, and causes peripheral arterial vasodilation, decreasing afterload (this dilation is abrupt and can cause hypotension in some patients). It is the drug of choice for severe heart failure.

Epinephrine is a potent sympathomimetic with varying effects based on the dose. The drug has β -mimetic effects at lower doses and α -mimetic effects at higher doses. Epinephrine causes

an acute increase in myocardial oxygen demand and is mainly reserved for cardiac arrest or severe circulatory failure. Norepinephrine and phenylephrine are pure α -mimetic agents, utilized for vasoconstriction (neurogenic shock). In most situations of shock, fluid resuscitation is preferred to administration of α -agents. Although these agents will give a false sense of security that the blood pressure is normal, one must remember that the vasoconstriction underperuses capillary beds, leading to an increased incidence of renal hypoperfusion (acute renal injury), splanchnic hypoperfusion (resulting in translocation of gut flora), and a myriad of other problems (220,221).

Vasopressin has emerged as an option similar to epinephrine, with some important differences. This antidiuretic hormone in high doses provides potent vasoconstriction and leads to improved cerebral and coronary blood flow in shock states. Unlike epinephrine, there is less increase in myocardial oxygen demand and less propensity for inducing arrhythmias.

Amrinone (or inamrinone) is a phosphodiesterase inhibitor that provides a positive inotropic effect on cardiac musculature while causing vasodilation. It is used in refractory cardiac failure.

Valvular Disease

In a recent study, approximately 4% of patients undergoing elective, noncardiac surgery were found to have clinically significant valvular disease. Important considerations in perioperative management are directed at patients with aortic stenosis (AS) and the level of associated ventricular failure. Aortic stenosis is an independent risk factor for poor operative outcome, as previously mentioned (222). Patients with severe AS need valve replacement before elective surgery, whereas patients with mild to moderate AS need careful anesthetic control of blood pressure. The presence of ejection systolic murmurs requires assessment of left ventricular function for the presence of congestive heart failure with echocardiography (223). Treatment and support will be related to support of ventricular function. Avoidance of systemic hypotension in the perioperative period is essential. Recently, the American Heart Association reviewed its recommendations for universal prophylactic antibiotic administration for prevention of endocarditis in patients with valvular disease and artificial valves, and patients who have had surgical correction of congenital defects who are undergoing gastrointestinal (GI) or genitourinary (GU) procedures. Routine administration of prophylactic antibiotics is no longer recommended. However, if patients have active GU or GI infections, then the surgery should be delayed, if possible, to allow eradication of the infection with antibiotic treatment. Any antibiotic regimen should include agents that are active against enterococci, such as ampicillin or vancomycin, and should be administered 30 minutes before to 2 hours after the procedure (224,225). Antibiotic prophylaxis may be reasonable for patients with prosthetic cardiac valves if the valves have been placed within the previous 6 months; previous history of infective endocarditis; or certain congenital heart diseases (CHD) such as unrepaired cyanotic CHD, any repaired CHD with prosthetic material within the previous six months, and any repaired CHD with residual defect adjacent to a prosthetic patch or device (which prevents endothelialization) (226).

Arrhythmias

Postoperative arrhythmias are often secondary to noncardiac problems such as hypotension, electrolyte abnormalities, hypoxia, or infection. Whenever an arrhythmia occurs in the postoperative setting, myocardial ischemia must first be ruled out (227). If ECG and cardiac enzyme measurements are normal, the arrhythmia is not likely to be due to myocardial ischemia. Fortunately, most arrhythmias in the postoperative period are transient and self-resolving. Asymptomatic arrhythmias, except in the preoperative period (Table 11.2), are generally of little clinical significance.

Hypercapnia, hypoxemia, hypokalemia, acidosis, inadequate analgesia, and anemia can all promote cardiac arrhythmias. Supraventricular tachycardia is the most common rhythm disturbance seen in the postoperative period (228). Treatment with calcium channel blockers (such as diltiazem) or a β -blocker is usually effective after correction of the underlying etiology. Amiodarone as first-line treatment of acute-onset postoperative atrial fibrillation has been associated with a lower incidence of recurrent atrial fibrillation (229).

Pulmonary Issues

Ventilator Management

The ability to provide ventilatory support to the surgical patient has been a tremendous advance in postoperative care. Mechanical ventilators have enabled oncologic surgeons to perform major operations for aggressive control of lesions that were once considered to be unresectable. Although preemptive preoperative therapies attempt to avoid postoperative mechanical ventilation, some patients will require this therapy. Mechanical ventilation must be thought of as providing 2 functions: ventilation and oxygenation. However, these 2 functions must be separated and applied independently to each particular situation. A more difficult concept for residents and fellows to understand is that ventilation has nothing to do with oxygenation. Many patients decompensate on the ward despite supplemental oxygen and 100% oxygen saturation because tidal volumes were low and the patient was not ventilating.

When contemplating mechanical ventilation, one must ask 2 questions: is the patient able to oxygenate her tissues adequately, and can she ventilate adequately to maintain normal partial pressure of carbon dioxide (PCO_2) and acid-base function? Adequate oxygenation can be determined by measurement of oxygen saturation and arterial partial pressure of oxygen (PO_2). Targets are generally an O_2 saturation $>92\%$ or PO_2 greater than 65 mm Hg. Poor oxygenation may be caused by fluid overload, depressed mental status, underlying pulmonary disease, or shunt. Evaluation of the arterial blood gas will also give a pH and PCO_2 measurement. Patients may hypoventilate for a number of reasons. Postoperative pain may prohibit deep inspiration. Conversely, overuse of pain medication may depress the level of consciousness, leading to fewer and poorer respirations. Atelectasis, pneumonia, and poor pulmonary compliance all lead to difficulties in ventilation. Finally, a bronchial mucous plug or a pneumothorax will lead to life-threatening ventilatory compromise. A respiratory rate greater than 35 per minute or a PCO_2 greater than 55 mm Hg are accepted indications for intubation and mechanical ventilation.

When intubating patients, the size of the endotracheal tube must be considered, as this may impact removal of mechanical ventilation. The larger the tube, the less resistance and the easier it will be for the patient to participate in “weaning” trials to discontinue ventilatory support (230). Typical recommendations are an 8.5-mm tube for women and a 9.0-mm tube for men.

Traditionally, there are pressure-cycled ventilators and volume-cycled ventilators. Pressure-cycled ventilators are used routinely in neonatal ICU patients because overinflation can be dangerous to neonates. In the adult ICU, most ventilators are volume-cycled, meaning that the clinician sets the tidal volume, and regardless of the pressures necessary to give the volume, the volume will be delivered. In patients in whom pulmonary compliance is reduced (i.e., due to a stiff lung or acute respiratory distress syndrome [ARDS]), efforts at controlling pressure are important. When setting the ventilator, a number of decisions must be made. The mode of delivery, tidal volume, and rate will determine ventilation, whereas the fraction of inspired oxygen (FIO_2) and positive end-expiratory pressure (PEEP) will determine oxygenation.

Mode

There are a number of ventilator modes. The first developed was controlled mechanical ventilation (CMV), where the tidal volume and rate are set and that is exactly what the patient receives—no more and no less. This mode is very good for patients under general anesthesia or who are paralyzed. However, this mode is very disturbing to the patient who wishes to participate, however slightly, in her own ventilation. This mode has evolved into the current assist/control mode (A/C), whereby the patient is guaranteed the fixed rate and tidal volume but can also trigger breaths in between with a similar tidal volume. In addition, the machine will synchronize the breath when the patient triggers such a breath. This mode provides complete rest for the patient by performing all the work of breathing and is generally used for patients in the immediate postoperative period or for patients who have critical illnesses such as organ failure or sepsis.

Intermittent mandatory ventilation (IMV) is a mode whereby the clinician sets a rate and a tidal volume, which the machine delivers. Any breath initiated by the patient is delivered in relation to the amount of effort the patient puts forth, meaning a strong effort gives the patient a large breath and a meager effort a smaller one. This is sometimes called a weaning mode. The patient is given full support with rate and tidal volume until she is stronger. The rate is slowly turned down, allowing the patient more frequent, spontaneous breaths until extubation. Synchronized IMV (SIMV) ensures that a machine-delivered breath does not stack onto a patient-initiated breath.

Pressure support ventilation (PSV) is a mode where patient-initiated breaths are given support from the ventilator only during the beginning of ventilation (inspiratory phase). The support is meant to help the patient overcome the large amount of resistance present in the valves of the machine, the ventilator circuit, and the endotracheal tube. By titrating PSV to the spontaneous tidal volume produced by the patient, one can fully or partially support patient breathing and overcome the work of breathing. This mode of ventilation is important during the “weaning” process.

Work of Breathing

When conceptualizing the job of the ventilator, the different types of work must be defined (230). In addition to the physiologic work of breathing that all humans do on a daily basis, huge workloads are imposed from the resistance of the ventilator equipment (e.g., breathing through a straw analogy). Finally, there is the pathologic work of breathing from pneumonia, the incision, etc. The intent of mechanical ventilation during disease states is to assume the last two types of “work” so that the patient may convalesce. As a patient improves and the pathologic work has been removed, then the patient should be able to resume normal, physiologic work.

More Advanced Modes of Ventilation

With advanced circuitry and computer microprocessors, newer ventilator modes have been developed. Pressure-regulated volume control (PRVC) has largely replaced AC ventilation (ACV). PRVC provides the same function as AC while preventing overinflation. Recent data have shown that preventing overinflation (or stretch) of alveoli prevents trauma and decreases the incidence of ARDS (231). PRVC delivers the same tidal volume but changes the flow rate to prevent high pressures by measuring the pressure on a breath-to-breath basis. Volume control (VC) ventilation is a mode whereby a tidal volume target is set and the ventilator continually titrates the amount of PSV to provide this volume. This mode has been termed “autowean” or “weekend” mode because as the patient gets stronger, he or she will be able to meet the tidal volume setting. In situations where difficulties in ventilation

are encountered, such as ARDS, hypercarbia, and acidosis, pressure control (PC) is used. This mode is similar to the neonatal pressure-cycled ventilator where the maximum pressure is set and the flow rate is decreased but the inspiratory time is lengthened to achieve proper ventilation. Airway pressure release ventilation (APRV), high-frequency jet ventilation, and inverse ratio ventilation are other advanced modes, the discussion of which is beyond the scope of this chapter.

Setting the Ventilator

Initial ventilator settings require a rate of 12 to 14 breaths per minute with a tidal volume of 6 to 8 cc/kg. This is a departure from the traditional 12 cc/kg, which has been determined to result in greater alveolar trauma and increased risk for the development of ARDS (232). After initial setting of the ventilator, measurements of pH, PO₂, and PCO₂ from arterial blood gas are used to make further ventilator adjustments.

Oxygenation

Oxygenation is controlled by two settings: FIO₂ and PEEP. The inspired oxygen content can easily be controlled with the ventilator, to keep blood oxygen saturation greater than 92%. Inspired oxygen concentration greater than 60% is considered to be potentially toxic and may be the etiologic reason for pathologic changes similar to ARDS. In patients with normal lung function, studies have shown that higher concentrations of inspired oxygen can cause acute inflammation and fibroproliferative changes, resulting in toxic effects to lung tissue. Similar studies in patients with underlying lung disease are lacking (233,234). If it is necessary to have oxygen concentrations above 60%, the recommendation is to wean these levels as soon as possible. PEEP is another mechanism for improving oxygenation. In normal physiology, the glottis closes before full expiration, creating a PEEP of approximately 4 cm H₂O, and is termed physiologic PEEP. When ventilating patients, the addition of 5 cm H₂O PEEP is used as a baseline and is increased if added oxygen delivery is required. Increasing PEEP is the preferred method for improving oxygenation in post-surgical patients as opposed to increasing the FIO₂. Postsurgical patients have atelectasis and shunting secondary to operative pain and anesthesia. The addition of PEEP recruits collapsed alveoli, improving oxygenation and lung compliance. However, the use of PEEP must be balanced by potential adverse effects, which include decreased cardiac output and the risk for barotrauma.

Weaning From Ventilator

Multiple opinions exist on the techniques of weaning patients from mechanical ventilation. T-piece trials, spontaneous breathing trials (SBT), SIMV, and PSV are just a few. The best method of weaning is a pathway agreed upon by clinicians, nurses, and respiratory therapists. Before discontinuing mechanical ventilation, the disease process that required ventilation should have resolved and patients should have proper mental status and the ability to generate a cough. Copious secretions are often an initial reason not to consider weaning or extubation. Criteria for extubation, whether on T-piece or minimal PSV, have traditionally included a respiratory rate less than 35, a PCO₂ less than 50 mm Hg, and a negative inspiratory force (NIF) greater than -20 cm H₂O. Rapid shallow breathing, defined as the respiratory frequency divided by the tidal volume in liters over a minute, is the most accurate predictor of failure in weaning patients from mechanical ventilation (235).

Acute Respiratory Distress Syndrome

ARDS is a condition that has been well recognized and extensively studied (236–238). This disease is a form of refractory hypoxemia which is caused by a variety of insults, which incites

an inflammatory response consisting of increased production of cytokines, leukotrienes, endothelial adhesion molecules, and interleukins. These molecules, which are useful in the defense of the host organism, are particularly detrimental to pulmonary endothelium. ARDS is the result of some inciting cause and does not arise *de novo* as a primary problem. A study of patients who develop multiple organ dysfunction syndrome (MODS), a state where sequential organ failure leads to patient death, has shown that the lung may be the first organ system susceptible to these circulating inflammatory mediators (239). In addition to supportive treatment for ARDS, operative injuries or postoperative complications (e.g., intra-abdominal abscess, anastomotic leak) must be sought and ruled out.

In 1994, a consensus of American and European intensivists defined the criteria for ARDS and a lesser form of the disease described as acute lung injury (ALI) (237). Criteria include (a) acute onset after defined insult; (b) bilateral diffuse infiltrates on chest radiograph; (c) no evidence of left atrial hypertension, CHF, or a PAOP less than or equal to 18 mm Hg; and, most importantly, (d) impaired oxygenation. Impaired oxygenation was classified as ALI if the partial pressure of arterial oxygen (PaO₂)/FIO₂ ratio was ≥300 mm Hg and ARDS if the PaO₂/FIO₂ ratio was ≥200 mm Hg. Postmortem examination of lungs with ARDS shows atelectasis, edema, inflammation, hyaline membrane deposition, and fibrosis. The mortality of ARDS is 30% to 40%. Treatment of these severely hypoxemic patients consists of mechanical ventilatory support with FIO₂ and PEEP. Because of alveolar damage, ventilation/perfusion mismatch occurs, resulting in a worsening shunt fraction and increasing dead space. As ALI/ARDS progresses, ventilation, due to decreased pulmonary compliance, becomes difficult and oxygenation progressively worsens. The end result is a hypercapnic state and respiratory acidosis.

The recent ARDS NET trial comparing high tidal volume, in order to maintain normocapnia, to low tidal volumes, to prevent barotrauma, showed significantly improved survival among patients in the low tidal volume group (231). Current strategies employ tidal volumes of 6 cc/kg, while accepting elevated PCO₂ levels (permissive hypercapnea).

Pneumonia

Pneumonia is a significant complication in postsurgical patients. Patients requiring mechanical ventilation are particularly susceptible to pneumonia (ventilator-acquired pneumonia [VAP]), with rates as high as 30% after 72 hours of ventilation. The mortality rate from VAP ranges from 25% to 50%. The pathogens are often gram-negative bacteria and are resistant to multiple antibiotics. High clinical suspicion and aggressive treatment of VAP is crucial. An exhaustive review of this complicated and serious topic by Chastre and Fagon is recommended for further reading (240).

Pulmonary Embolism and Deep Venous Thrombosis Prophylaxis

The prevention of venous thromboembolism is an important component of perioperative management of the gynecologic oncology patient. The American College of Chest Physicians consensus statement published in 2012 reviews the data exhaustively and provides recommendations (241). Patients undergoing major gynecologic surgery without venous thromboembolism prophylaxis have a risk of deep vein thrombosis (DVT) between 17% and 40% (242). Surgery for cancer, advanced age, previous VTE, prior pelvic radiation therapy, and abdominal resection (in contrast to vaginal resection) appear to increase the thromboembolic risk after gynecologic surgery (243). The incidence of pulmonary embolism (PE) is 1.6% with rate of fatal PE being 0.9%. In trials comparing low-dose unfractionated heparin (LDUH) with no therapy in general surgical patients, the DVT rate was decreased

from 25% to 8%. These studies also produced a 50% decrease in the rate of fatal PE (244). Comparisons of low-molecular-weight heparin (LMWH) versus LDUH have shown equal efficacy. LMWH may have fewer complications (mostly wound hematomas) and greater ease of use with once daily dosing.

Sequential pneumatic compression devices (PCDs) are attractive for patients at risk for bleeding complications. In trials comparing PCD with LDUH, both have shown efficacy. Elastic stockings T.E.D. hose and aspirin usage are not currently recommended for DVT prophylaxis. Studies have shown that the presence of D-dimer positivity in the face of DVT and/or PE, but the presence of any released blood or hematoma (i.e., in any post-operative patient) makes the D-dimer positivity nonspecific. In the surgical patient, a negative D-dimer makes DVT or PE highly unlikely; however, a positive test is essentially useless.

Patients at low risk (age less than 40 years, no risk factors, and minor surgery) need no prophylaxis, but early ambulation is encouraged. Moderate-risk patients (minor surgery in a patient with risk factors, major surgery with no risk factors) should receive PCD, LMWH, or LDUH, with equal results. High-risk patients require LMWH in addition to PCD.

Diagnosis of DVT is performed by duplex ultrasonography, and treatment is with either heparinization to 1.5 times control prothrombin time or therapeutic doses of LMWH. Diagnosis of PE was traditionally made by pulmonary arteriogram. This practice has been abandoned because dynamic contrast-enhanced computerized tomography has better sensitivity. Once diagnosis is confirmed, the patient is anticoagulated with IV heparin or LMWH. Ultimately, the patient is converted to warfarin (Coumadin) therapy for at least 3 months in the case of DVT and PE (241).

Fluid and Electrolyte Issues

Understanding fluid and electrolyte physiology in gynecologic oncology is paramount because of the underlying disease processes that face the gynecologic oncologist and the ultimate, radical surgical interventions that are needed to treat them. These treatments result in great fluid shifts perioperatively, requiring careful attention to input of fluids (volume and content/type) as well as output from renal and gastrointestinal sources, insensible sources, and drains. Since extensive discussions of these topics can be found elsewhere, this section presents a brief review of normal fluid and electrolyte physiology and discusses strategies for fluid resuscitation and correction of electrolyte deficiencies.

Total body water (TBW) can be calculated by a variety of methods and varies directly with the amount of adipose or lean tissue present in an individual patient. TBW estimates, therefore, must be adjusted based on the adiposity of the patients. In women, TBW accounts for approximately 60% of a patient's weight. TBW is distributed into extracellular fluid (ECF) and intracellular fluid (ICF), with the ECF being further divided into intravascular (one-quarter of the ECF) and interstitial (three quarters of the ECF) compartments. The ECF accounts for approximately one-third of the TBW, whereas ICF accounts for two thirds (245,246). Direct measurement of the ECF and TBW are possible with the resulting difference being an estimated ICF. Table 8.13 describes the body fluid compartments and their contributions to body weight. Despite these arbitrary compartments (and electrolyte concentration differences between compartments, which are discussed in the paragraph below), water flows freely across all compartments. Thus, a derangement in one compartment will result in a compensatory change in another (247).

The electrolyte composition of the various compartments is different. Sodium is the predominant cation in the ECF and potassium is the predominant cation of the ICF. Table 8.14

Table 8.13 Body Fluid Compartments

Total Body Water	Body Weight (%)	Total Body Water (%)
Total	60	100
Intracellular	40	67
Extracellular	20	33
Intravascular	5	8
Interstitial	15	25

describes the various concentrations of electrolytes in the various fluid compartments. Because of the Donnan principle of equilibration, the content of cations and anions in the interstitial compartment is slightly higher than in the intravascular compartment. This principle describes the unique relation between solutions of permeable and impermeable complex anions when these anions are unevenly distributed across a semipermeable membrane. Water, on the other hand, as mentioned earlier, freely equilibrates between the compartments (247).

Effective circulating volume (ECV) is a term used to describe the portion of the ECF that perfuses the organs of the body and affects baroreceptors (see next paragraph). In healthy patients, the ECV equates to the intravascular volume/compartment. But in disease states that increase “third spacing” such as sepsis (leaky capillaries), ascites due to intra-abdominal metastasis, or bowel obstruction with resulting edema and transudation, the interstitial compartment increases at the expense of the intravascular compartment, decreasing the ECV (245).

The osmotic activity of a fluid compartment is affected by the component ions and is described in milliosmoles (mOsm). Normal serum osmolality (in the ECF, of course) averages 290 mOsm/kg of H₂O. Osmoreceptors in the hypothalamus

respond to small changes in serum osmolality, increasing or decreasing secretion of antidiuretic hormone (ADH) and modifying the thirst response. These receptors are responsible for the day-to-day fine-tuning of fluid balance. Baroreceptors, on the other hand, in the intrathoracic vena cava, the atria, the aortic arch, the carotid arteries, and the renal parenchyma, sense volume changes by changes in pressure. These receptors begin a cascade of mediators such as aldosterone, atrial natriuretic peptide (ANP), prostaglandins, and the renin-angiotensin system, which ultimately result in changes of water and sodium balance mediated through the kidneys. These baroreceptors have little to do with the day-to-day fluid management and require intravascular losses of 10% to 20% to initiate activity (247).

The goal of fluid resuscitation is to maintain the ECV and return the patient to a homeopathic state. Many gynecologic oncology procedures are lengthy and can result in large blood losses requiring immediate intraoperative replacement. In addition, following procedures where evacuation of large amounts of ascites has occurred and/or “peritoneal stripping” has left denuded surfaces, these patients may have large fluid shifts into the interstitial compartment, requiring large volumes of fluid to maintain the ECV. Finally, losses are not water alone and include electrolytes and clotting factors, which may need repletion. Selecting fluids to administer to a given patient is akin to selecting the correct intravenous medication to give; not *all* fluids are for *all* patients. The physician should understand the amount of daily maintenance fluid and electrolytes required by patients, calculate losses (fluid and electrolytes), determine ongoing fluid and electrolyte losses, and replace them with the appropriate fluid and electrolyte combinations. It is easy to fall into the trap of giving all patients an 8-hour rate (125 mL/hour) of maintenance fluid. However, an octogenarian, even with normal cardiac and renal function, weighing 50 kg does not need that much maintenance fluid. “Formulas” for calculating appropriate maintenance fluid requirements exist (247), but calculating 30 to 40 mL/kg/day, depending upon body frame size, is a much simpler and quicker estimate of maintenance fluid requirements for patients.

In general, the normal maintenance requirement of sodium is 1 to 2 mEq/kg/day and for potassium 0.5 to 1.0 mEq/kg/day. Table 8.15 lists the various IV fluid preparations available for fluid resuscitation. Which fluid to be used is controversial and driven, in more instances, by “dogma,” varying from physician to physician and institution to institution; rather than by evidence. Controversy over which fluid type to use in fluid resuscitation continues to this day. Several meta-analyses have shown no advantage of colloid over crystalloid for resuscitation in surgical patients (248–255). Almost all studies have shown that administered colloid leaks from the intravascular compartment to the interstitial compartment in several hours, decreasing the ECV and requiring further administration of colloid (248–255). The use of colloid has been shown to be advantageous in conditions of hypoproteinemia, or in malnourished states where patients require plasma volume expansion and cannot tolerate large amounts of fluid (255).

Most of the time patients are given isotonic solutions, such as lactated Ringer’s solution, to cover perioperative losses. In the immediate postoperative course, patients are given their maintenance fluid requirements in addition to the immediate intraoperative losses. It is helpful to convert all losses to equivalents of crystalloid to determine fluid rates. For example, to replace 500 mL of blood loss, one would give 1,500 mL of isotonic fluid, a ratio of 3 mL of crystalloid to 1 mL of blood loss. It is traditional to replace one-half of the intraoperative losses in the first 24 hours, with the rest being replaced during the ensuing several days. Other intraoperative losses, which need to be accounted for, are the insensible losses that occur through evaporation from the incision (5 to 10 mL/kg/hour of operation) and from the anesthesia circuit and ascites.

Table 8.15 Electrolyte Content of Commonly Used Intravenous Electrolyte Solutions

Solution	Electrolyte Concentration (mEq/L)					
	Na ⁺	K ⁺	Ca ₂ ⁺	Mg ₂ ⁺	Cl ⁻	HCO ₃ ⁻
Lactated Ringer’s solution	130	4	4	—	109	28

Sodium Derangements

Hyponatremia is the most common electrolyte abnormality seen in postoperative patients and is caused by excess free water rather than a depletion of sodium. Increases in free water absorption are mediated by a self-limited, physiologic increase in the secretion of ADH in response to the stress of surgery. Serum sodium levels rarely fall below 130 mEq/L, but may be further exacerbated by intravenous administration of large volumes of hypotonic solutions (i.e., 0.2%, 0.33%, and 0.45% sodium solutions). Other disease states can result in a hyperosmolar condition, resulting in a hyperosmolar ECF, causing fluid to shift from the ICF and lowering the sodium levels. These conditions include hyperglycemia; mannitol, ethylene glycol, or ethanol ingestion; and uremia. For each increase of 180 mg/dL of glucose above 100 mg/dL, there is a concomitant decrease in the serum sodium of 5 mEq/L (254). In addition, during situations where potassium is low, there is a compensatory exchange of sodium for potassium, resulting in hyponatremia. In either of these prior cases, total body sodium does not change. Finally, patients with hyperproteinemia or hyperlipidemia may have falsely low sodium values, which result from errors in the laboratory measurement of sodium. This *pseudohyponatremia* does not result in any symptoms of hyponatremia (247).

The symptoms of hyponatremia are driven by cellular water intoxication and are related to the central nervous system (CNS) (e.g., lethargy, headaches, confusion, delirium, weakness, muscle cramps). The rate at which hyponatremia occurs also determines the symptoms. Chronic hyponatremia tends to be asymptomatic, whereas acute drops in the serum sodium (levels 120 to 130) result in the symptoms listed above. Correction of hyponatremia must be done carefully to avoid central pontine myelinolysis, which results in the “locked-in syndrome.”

Because most hyponatremia is related to dehydration (low ECV) simple correction of this state will increase the sodium plasma level. If the patient has a high ECV (such as the syndrome of inappropriate antidiuretic hormone [SIADH] secretion) or is in an edematous state, free water restriction should normalize the sodium level. However, if patients have symptoms of hyponatremia, aggressive replacement of sodium is prudent should the duration of the hyponatremia be determined to be no longer than 48 hours. Hyponatremic states lasting longer than 48 hours increase the risk of central pontine myelinolysis. Chronic cases need replacement at rates not to exceed 0.5 mEq/L/hour. Acute cases may be replaced at rates of 5 mEq/L/hour.

Hypernatremia is an uncommon finding and is related to large volumes of free water loss (through insensible routes such as breathing, sweating, and ventilation), diabetes insipidus, adrenal hyperfunction, or ingestion or administration of increased sodium solutions. Again, the symptoms are predominantly CNS oriented because of brain cell dehydration. Symptoms rarely occur until serum sodium levels exceed 160 mEq/L. In addition, the rapidity at which the derangement occurs determines the symptoms manifested. Treatment is carefully done with replacement of free water. Replacement too rapidly can cause cerebral edema and herniation. Patients with chronic hypernatremia need free water administration, which decreases the serum sodium no faster than 0.7 mEq/L.

Potassium Derangements

Whereas sodium is the major extracellular cation, potassium is the major intracellular cation by a ratio of 30:1. The intracellular potassium concentrations tend to be relatively constant, whereas the extracellular concentrations vary depending upon renal function/excretion. The majority of potassium secretion occurs in the distal tubule and the collecting duct of the nephron. Secretion is stimulated by increased urine flow, increased sodium delivery, high potassium levels, alkalosis, aldosterone, vasopressin, and β -adrenergic agonists. Insulin causes potassium to move into cells (as previously mentioned), reducing the extracellular concentration of potassium. Serum potassium levels are further affected by the acid-base status of patients. In alkalotic states, the potassium shifts into cells in exchange for hydrogen ions, whereas in acidotic states the exchange is opposite.

The predominant reason for hyperkalemia in a postoperative patient is renal dysfunction or failure. When these patients become critically ill, serum potassium concentrations can increase by 0.3 to 0.5 mEq/L/day in noncatabolic patients and 0.7 mEq/L/day in catabolic patients. It is important to rule out a spuriously elevated level secondary to hemolysis at the time of the blood draw either from too small a gauge of needle or simply from the application of the tourniquet and squeezing (247).

Hyperkalemia changes the membrane potential established by differences between the intracellular and extracellular milieu. This increased concentration has deleterious effects on cardiac muscle function, causing peaked T waves, flattened P waves, prolonged QRS complexes, and deep S waves on the ECG, and possibly resulting in ventricular fibrillation and cardiac arrest. Skeletal musculature is also affected with paresthesias and weakness, which can progress to a flaccid paralysis.

Treatment for hyperkalemia has been outlined in the section on renal risk factors. The mainstay is saline diuresis unless ECG changes are present, then infusion of calcium gluconate can be lifesaving. Utilization of 25 to 50 g of glucose and 10 to 20 units of regular insulin can drive potassium intracellularly and transiently lower plasma levels. Ultimately, definitive therapy relies upon increased excretion of potassium. For each gram of sodium polystyrene sulfonate (Kayexalate, given in the doses previously mentioned) used either orally or rectally, 0.5 mEq of potassium will be removed. Finally, in patients not responding to these therapies or patients with renal failure, hemodialysis may be indicated.

Hypokalemia is caused by decreased intake, increased gastrointestinal losses (vomiting, diarrhea, fistulae), excessive renal losses (metabolic alkalosis, magnesium deficiency, hyperaldosteronism), a shift of potassium into the intracellular space (acute or uncompensated metabolic alkalosis, glucose and insulin administration, catecholamines), or any combination thereof. A reduction of serum potassium by 1 mEq/L represents a total body deficiency of about 100 to 200 mEq. (Remember that total exchangeable potassium is approximately 3,000 mEq, with the majority being intracellular and thus the majority of the loss [247].) Symptoms of hypokalemia cause ECG changes with

flattening of the T waves, depression of S-T segments, prominent U waves, and prolongation of the Q-T interval. Treatment is accomplished by replacement of potassium either orally or intravenously, depending upon the severity of symptoms and whether or not the patient is able to take oral preparations. Intravenous replacement of potassium can be done at approximately 10 mEq/hour and should not be more concentrated than 40 mEq/L. If less fluid is desired, 20 mEq can be placed in 100 mL, but administration should not exceed 40 mEq/hour (247).

Magnesium Derangements

Most magnesium in the body is confined to the intracellular space and bone. Less than 1% of total body magnesium is in the serum. Of the magnesium in the serum, 60% is ionized, 25% is protein bound, and 15% is complexed with nonprotein anionic species (247). Magnesium is absorbed in the small intestine, directed by levels of vitamin D, and filtered by the kidney for excretion. Approximately 40% of renally excreted magnesium is reabsorbed in the ascending loop of Henle. Loop diuretics, hypermagnesemia, hypercalcemia, acidosis, and phosphate depletion result in increased excretion of magnesium.

Patients with renal failure and receiving magnesium-containing antacids or laxatives can become hypermagnesemic. In addition, patients with acidosis and dehydration may become hypermagnesemic. Patients present with CNS depression, loss of deep tendon reflexes, and ECG changes (prolonged P-R interval and QRS complex) in the face of elevated magnesium levels (greater than 8 mg/dL). As levels rise, patients will develop coma, respiratory failure, and/or cardiac arrest. Acute treatment of hypermagnesemia is slow IV infusion of 5 to 10 mEq of calcium. Because the etiology of this condition is usually renal failure, withholding magnesium-containing preparations may be all that is necessary. In severe instances, hemodialysis is required.

In gynecologic oncology patients, the overwhelming reason for hypomagnesemia is a history of cisplatin administration. However, other conditions such as hypoparathyroidism, malabsorptive states, chronic loop diuretic use, and the diuretic phase of acute renal failure can cause hypomagnesemia. Symptoms are similar to hypocalcemia, with muscle weakness, fasciculations, tetany, hypokalemia, and ECG changes (Q-T prolongation, torsade de pointes). Treatment can be accomplished with oral preparations in less acute situations. However, large doses may produce diarrhea, worsening the situation. Intravenous boluses of 2 to 3 g followed by infusions of 1 to 2 mEq/kg/day can be utilized for patients with severe symptoms.

Calcium Derangements

Almost all the calcium in the body is in bone, stored as hydroxyapatite crystals, and provides a supply that can be exchanged to the serum. Calcium homeostasis is controlled by parathyroid hormone (PTH), controlling intestinal absorption of calcium, renal excretion of calcium, and exchange of calcium from the bone. In the serum, calcium exists in three phases: 45% as an ionized form, which is responsible for most of the physiologic function of calcium; 40% in a protein bound form, bound mostly to albumin; and 15% in a nonionized form, complexed with nonprotein anions that do not easily dissociate. A serum total calcium level is usually obtained when assessing calcium homeostasis, as measurement of ionized calcium is cumbersome. The total calcium levels change by 0.8 g/dL for each 1 g/dL change of albumin (up or down) (247).

In gynecologic oncology patients with hypercalcemia, the underlying malignancy is usually the etiologic agent. Hypercalcemia may be caused by direct bony involvement or, more commonly, secretion of PTH-like peptides and/or other humoral factors, which increase serum calcium levels. Other reasons for hypercalcemia include primary, secondary, or tertiary hyperparathyroidism,

thiazide diuretic use, or lithium usage (247,256). Patients present with muscle fatigue, weakness, confusion, coma, ECG changes (shortening of the Q-T interval), nausea, and vomiting. The goal of treatment is to increase calcium excretion and stop bone turnover in order to decrease serum total calcium. Initial measures include vigorous hydration (200 mL/hour) with 0.9% or 0.45% saline solutions. Furosemide or other loop diuretics may be helpful in patients with borderline cardiac function or in patients with fluid overload. If the underlying malignancy is a breast carcinoma, patients may respond to high doses of steroids to reduce calcium levels. Other pharmacologic agents have been developed to stop bone resorption and reduce serum calcium levels. Calcitonin (4 IU/kg every 12 hours via subcutaneous or intramuscular injection) has a rapid onset of action and works by interfering with osteoclast maturation at several points (256). However, the duration of response is usually about 48 hours because of downregulation of calcitonin receptors by osteoclasts. Bisphosphonates have emerged as the drug of choice for treatment of hypercalcemia in malignancy. These agents work by inhibiting osteoclast activity and survival. The nitrogen-containing bisphosphonates are the most potent. Pamidronate (approved in 1991) and zoledronic acid (approved in 2001) are utilized in the United States. Another agent, ibandronate, is utilized in Europe but has not been approved for use in the United States. Zoledronic acid is the current drug of choice because of its proven superiority over pamidronate (257). The effective dose of zoledronic acid is 4 mg infused over 15 minutes and dosed every 3 to 4 weeks. Serum calcium levels return to normal in approximately 10 days and duration of response lasts approximately 40 days (258). Surgical resection is the treatment of choice for primary, secondary, or tertiary hyperparathyroidism (246,256).

Hypocalcemia is caused by hypoparathyroidism, hypomagnesemia, pancreatitis, and malnutrition. Patients present with tetany, hyperactive deep tendon reflexes, a positive Chvostek sign, positive Trousseau sign, and ECG changes (prolonged Q-T interval, prolonged S-T segment). Low levels of calcium may be present because of low albumin levels, but these levels do not affect the ionized portion of calcium and usually do not cause symptoms. Symptomatic hypocalcemia can be treated with intravenous infusion of either calcium gluconate or calcium chloride at a rate not to exceed 50 mg/minute. Calcium chloride dissociates into the ionized form of calcium more readily and is the treatment of choice to raise serum ionized calcium level.

Acid-Base Disturbances

Optimum cellular function requires a very narrow range of pH for chemical reactions to occur normally. Several buffering systems exist within the body to maintain this optimum pH. The predominant buffering system is the carbonic acid-bicarbonate buffering system. Derangements in the concentration of bicarbonate (HCO_3^-) or in concentrations of carbon dioxide (CO_2) result in acid-base disorders. Because the kidneys control excretion/generation of bicarbonate and the lungs exchange CO_2 , these organs play a central role in the compensation of any acid-base disorder. Therefore, 4 situations arise in acid-base balance: metabolic acidosis and alkalosis, and respiratory acidosis and alkalosis. Compensatory mechanisms exist in each situation in order to blunt the effect on pH (Table 8.16).

Metabolic Acidosis

Most clinically significant metabolic acidosis occurs with a net loss of bicarbonate either due to direct loss or when consumption is greater than generation. Situations where extra renal losses of bicarbonate occur include diarrhea, gastrointestinal fistulae, and urinary diversions (ureterosigmoidostomy or ureteroileostomy, which result in reabsorption of NH_4Cl from urine). Certain disease states result in the production of organic acids

Table 8.16 Concentrations of HCO_3^- and PCO_2 in Primary Acid-Base Derangements and the Compensatory Response

Disorder	Primary		Compensatory Response		
	pH	HCO_3^-	PCO_2	HCO_3^-	PCO_2
Metabolic acidosis	↓	↓			↓
Metabolic alkalosis	→	→			→
Respiratory acidosis	↓		→	→	
Respiratory alkalosis	→		↓	↓	

Source: Adapted from Wait RB, Kahng KU, Dresner LS. Fluid and electrolytes and acid-base balance. In: Greenfield LJ, Mulholland M, Oldham KT, et al., eds. *Surgery: Scientific Principles and Practice*. 2nd ed. Philadelphia, PA: Lippincott-Raven Publishers; 1997:242–266, with permission.

(ketoacidosis and lactic acidosis), which consume bicarbonate and outpace the renal compensatory mechanisms. Similarly, overdoses of certain drugs (e.g., aspirin) or ingestion of toxins (e.g., ethylene glycol, methanol) consume bicarbonate and outpace the renal compensatory mechanisms. Renal acidosis occurs when the intrinsic acid-excreting function of the kidney malfunctions, resulting in retention of acid and consumption of bicarbonate without concomitant regeneration of bicarbonate. These are classified as renal tubular acidosis (RTA I, distal tubule dysfunction; or RTA-II, proximal tubule dysfunction). Cardiac effects are the major findings in metabolic acidosis (peripheral arteriolar dilation, decreased cardiac contractility, and central venous constriction). Other manifestations of metabolic acidosis include gastric distention, abdominal pain, nausea, and vomiting. In surgical patients, lactic acidosis is the primary cause of metabolic acidosis and results from tissue hypoperfusion. Therefore, treatment should be aimed at increasing tissue perfusion with fluid and blood administration. The use of bicarbonate is best reserved for patients with other, not easily reversible causes of metabolic acidosis. Older patients and patients with CVD may benefit from administration of bicarbonate. Administration should be instituted when the pH is 7.1 to 7.2. One or 2 ampules of bicarbonate (approximately 55 mEq/amp) can be administered intravenously, with further administrations being dictated by the pH obtained from an arterial blood gas measurement. In diabetic ketoacidosis, treatment with insulin and glucose infusion should not only reverse the acidosis but also treat the hyperglycemia.

Metabolic Alkalosis

Sustained metabolic alkalosis is an uncommon clinical entity and is related to renal dysfunction. Loss of HCl is the most common reason for an increase in extracellular bicarbonate. This situation occurs with prolonged nausea and vomiting or prolonged nasogastric suctioning of gastric contents. As acid is removed from the gastrointestinal tract, a net gain of bicarbonate occurs. Other situations that can result in metabolic alkalosis include volume contraction, exogenous administration of bicarbonate or bicarbonate precursors (citrate, lactate, or calcium carbonate), hypokalemia, hypercalcemia, hypochloremia, excess mineralocorticoid usage, and high PCO_2 . Patients rarely present with symptoms, as metabolic alkalosis occurs gradually. However, in patients who develop this situation acutely, most symptoms are CNS oriented (e.g., confusion, stupor, coma, muscle fasciculations, tetany). Correction of the underlying disease state usually corrects the metabolic alkalosis. Repletion of electrolyte abnormalities and infusion of appropriate fluids (chloride containing) restore volume and result in normal renal excretion of excess bicarbonate.

Respiratory Acidosis

A depression of the pH occurs when there is hypoventilation. This occurs secondary to airway obstruction, COPD, depression of the respiratory center, impaired excursion of the thorax, or inappropriate ventilatory management in the mechanically ventilated patient. Development of symptoms depends upon the chronicity or acute nature of the event. If chronic, most patients have no symptoms. If it is an acute change, drowsiness, restlessness, headache, or development of a flapping tremor may occur. Treatment of this condition is aimed at the underlying cause of the hypoventilation. In chronic conditions, the hypoxemia, and subsequent hypercapnia, resulting from the hypoventilation may be the sole drive for the patient's respirations. Correction of the hypoxemia may further worsen the respiratory acidosis and must be considered. In general, correction of the PCO_2 must be done slowly because re-equilibration of cerebral bicarbonate concentration lags behind systemic changes (247).

Respiratory Alkalosis

Respiratory alkalosis occurs when the PCO_2 decreases with hyperventilation. Hyperventilation may occur because of hypoxia, drugs, decreased lung compliance, and mechanical ventilation. With drops in the arterial PO_2 , the peripheral chemoreceptors (in the carotid and aortic body) sense this change and result in hyperventilation to increase arterial PO_2 with a resulting decrease in PCO_2 . Because of renal compensatory mechanisms, this condition is usually asymptomatic. However, in acute situations, patients may have a sensation of breathlessness, dizziness, nervousness with altered levels of consciousness, and tetany. Treatment of underlying hypoxia should address the hyperventilation. If acute symptoms are present, having the patient rebreathe expired air should temporarily relieve the symptoms.

Postoperative Nutritional Issues

As mentioned earlier, the full consideration of nutrition in the gynecologic oncology patient is presented in Chapter 33. In this section, we will discuss early refeeding in the postoperative gynecologic oncology patient, indications for enteral nutrition, and total parenteral nutrition (TPN).

Although malnutrition has been shown to be prevalent among gynecologic oncology patients (126,127), many patients are adequately nourished, undergo surgery uneventfully, and have return of bowel function in 2 to 5 days while simultaneously resuming oral intake. Recently, several prospective randomized trials have been conducted that demonstrate the utility of early refeeding in the postoperative period. In these studies, patients in the early feeding group were fed on the first postoperative day, with 90% or more tolerating diets. The underlying malignancies, types of operations, and complications occurred at similar rates between the early refeeding and the "traditionally fed" patients in all the studies. The placement of nasogastric tubes (NGTs) for intolerance of diet was low among the studies (less than 10% incidence). Finally, length of hospital stay was shorter among the earlier fed patients (258–264).

The use of the enteral route is preferred in sustaining or repleting patients in the postoperative period after extensive procedures. Enteral nutrition utilizes normal physiologic absorptive mechanisms, maintains gut epithelial integrity, and reduces infectious morbidity (265,266). Studies on nutrition have found that the splanchnic circulation and support of the mucosal integrity of the small bowel may prevent progression to MODS (Multi-Organ Dysfunction Syndrome). Specifically, the intestinal mucosa will atrophy secondary to lack of luminal nutrients and intermittent activation of the destructive cytokine pathways, and/or intermittent translocation of bacteria into the blood stream will occur. These events result in "priming" neutrophils, which ultimately leads to a full-blown systemic inflammatory response,

causing organ damage. A number of well-designed randomized trials have compared early enteral feeds to TPN in patients with pancreatitis, major elective surgery, and trauma (265,266). All of these studies have shown a clear benefit for early enteral feeding, with a decrease in infectious complications (266).

Although considered a nonessential amino acid in nourished, healthy patients, glutamine has emerged as an essential amino acid in patients who are stressed and critically ill. This amino acid has been shown to be an important component in maintaining enterocyte integrity and has now been added to most enteral preparations (265,266).

Enteral feeds may be given in a variety of fashions, and each is associated with its own type and number of complications. Intra-gastric feeds may be accomplished with NGTs, oral-gastric tubes, or percutaneous endoscopic gastrostomy tubes (PEGs). Intra-gastric feeding has the advantage of utilizing the stomach as a reservoir for bolus feeding. In addition, stretching of the stomach stimulates the biliary-pancreatic axis, which may be trophic to the small bowel. Finally, the gastric secretions mix with the feeding material and decrease the osmolality, thus reducing the incidence of diarrhea. The main disadvantage of this route of enteral feeding is the increased risk of gastric overdistention with high residual amounts of feeding material and the increased risk of aspiration pneumonia (265). Enteral feeds may also be accomplished through the placement of nasal tubes, which are positioned into the pylorus, duodenum, or jejunum (such as Dobhoff tubes). These tubes have the advantage of being placed (or migrating) more distal in the upper gastrointestinal tract, greatly reducing the risk of aspiration. These types of tubes are preferred in patients who require long-term ventilation. Because of advances in endoscopic instrumentation, many of the tubes can be placed via this method. At the time of laparotomy, gastrostomy, or jejunostomy, tubes (such as a Stamm or Witzel tube) may be placed. These have the advantage of being placed at the time of major abdominal surgery under direct visualization/palpation. The techniques are described in other texts (265,267). Several enteral feeding preparations are available, but vary from hospital to hospital depending upon formulary makeup. The use of the enteral route is contraindicated in patients with mechanical intestinal obstructions, and for these patients nutritional support can be accomplished through the parenteral route.

TPN took the forefront in nutritional sustenance and replacement in the 1980s. The basic premise of TPN is to provide dietary precursors to maintain anabolic function. TPN can be broken into 3 components of replacement: glucose and lipid preparations for normal or increased energy expenditures, and amino acid preparations for protein synthesis. Because of the higher osmolar load presented by these preparations, central venous access is necessary for administration. Subclavian, internal jugular, or peripherally inserted central catheters (PICCs) will need to be placed, and they present the first of several potential complications associated with TPN administration. At the time of placement, pneumothorax, intubation of arterial structures, air embolism, or cardiac arrhythmias may occur. Later complications include the possibility of infection at the skin entrance site or line sepsis. Should these infectious complications occur, removal of the catheter and antibiotic administration will be necessary (266).

The Harris-Benedict equation is utilized to calculate basal energy expenditure (BEE) for patients and approximates the BEE of a sedentary, fasting, nonstressed individual (268):

$$BEE = 666 + (9.6 \times \text{weight [kg]}) + (1.7 \times \text{height [cm]}) - (4.7 \times \text{age [yr]})$$

Because stress of disease and surgical intervention need to be considered, "stress factors" have been developed and are multiplied by the BEE to arrive at kilocalories per day. Stress level multipliers are 1.2 for a resting individual, 1.3 for an ambulatory individual or moderate stress (e.g., systemic inflammatory response syndrome [SIRS], sepsis), and 1.5 for severe stress/burn patients.

After calculation of caloric requirements, the composition of the TPN solution to be administered should be determined. Because there are many different types of TPN preparations available, consultation with the nutrition team or pharmacists in an individual hospital is necessary to arrive at the desired solution.

In aerobic situations, glucose is the primary substrate for energy expenditure. It provides 3.4 kcal/g and is usually given in a concentrated form in order to provide 70% of the calculated calories. The remaining 30% of calories is provided by lipid preparations. Not only does this component have denser caloric content (it provides 9 kcal/g), but administration precludes the development of a fatty acid deficiency. Adjustment of the composition of TPN may be necessary depending upon the disease state (e.g., more contribution of kilocalories from fat vs. carbohydrate in a ventilated patient because of the respiratory quotient of fat vs. glucose).

Protein requirements are provided by amino acid solutions and are determined by the patient's age, sex, nutritional status, ongoing stress, and comorbid conditions. In general, 25% of protein requirements are obtained by normal oral intake. The remaining protein comes from breakdown of serum and organic proteins. Thus, periods of prolonged malnutrition, with decreased protein intake, and increased stress of disease will lead to breakdown of visceral protein. An estimate of maintenance protein requirements is 1 g nitrogen per kilogram of body weight. In situations of increased stress, the patient may need 1.2 to 1.5 g/kg in order to maintain and/or replace protein losses. Table 8.17 shows serum protein measurements and their respective half-lives, which are useful for determining anabolic versus catabolic response to TPN treatment. Another method to assess nitrogen balance (positive or negative) is (265):

$$\text{Nitrogen balance} = \text{protein intake} / 6.25 - (\text{urinary urea nitrogen} + 4)$$

The amount of protein intake is divided by 6.25 to give the grams of nitrogen taken in. The urinary urea nitrogen is expressed in grams based upon a 24-hour collection. The correction factor of 4 is meant to adjust for the grams of nitrogen lost in the stool or non-urea nitrogen losses.

In addition to these three main components of TPN, daily requirements of vitamins, trace elements, and insulin are necessary to maintain/regain nourishment. Again, these preparations vary by hospital formulary and need consultation with resident pharmacists.

The rate of infusion of TPN needs to be titrated upward to take into account the large glucose load that the patient will be receiving. This lower rate allows the pancreas time to increase insulin secretion in order to meet the glucose load being presented. Similarly, the rate of infusion needs to be decreased when TPN is being stopped to prevent hypoglycemia. During TPN

administration, blood glucose measurements by finger stick are required so that hyperglycemia is avoided. For the first several days, measurement of serum electrolytes, with adjustments being made daily, is necessary.

As previously mentioned, complications from venous access are some of the drawbacks of TPN administration. Other complications include metabolic derangements, which most often are mild but need correcting as soon as they are identified, abnormalities of liver function tests, the clinical significance of which is unclear (267), and cholelithiasis/cholecystitis secondary to gallbladder sludge.

Renal Issues

Acute renal failure (ARF) or hospital-acquired renal insufficiency (HARI) continues to be a common problem among postsurgical patients. Although the incidence of HARI is 1.5 patients per 1,000 admitted, the impact of HARI on morbidity and mortality is quite high (mortality averages 45% but may exceed 80% if dialysis is required). The best methods for preventing HARI are reducing risk factors and reversing the condition by early detection and intervention (269).

When HARI presents in the postoperative patient, causes can be divided into 3 parts: prerenal, renal, or postrenal (inflow, parenchymal, and outflow). The function of glomeruli to create the urinary filtrate depends upon adequate renal perfusion and represents the prerenal component. If the renal mean arterial pressure (MAP) falls below 80 mm Hg, perfusion of the glomeruli decreases (some disease states require the renal MAP to be higher for adequate perfusion). Many situations can decrease renal MAP and include anesthetics, atherosclerotic emboli, decreased vascular resistance, hypotension, intravascular volume contraction, mechanical ventilation, sepsis, and any form of shock. Autoregulation of the glomeruli can be disrupted by nonsteroidal anti-inflammatory drugs (NSAIDs), angiotensin-converting enzyme (ACE) inhibitors, calcium channel blockers (diltiazem or verapamil), and endotoxins produced by gram-negative sepsis.

Renal parenchymal damage occurs most commonly in the postoperative patient because of prolonged hypotension or direct injury from inflammatory responses initiated by sepsis. In general, if the hypoperfusion is corrected quickly, reversible azotemia, creatinine elevation, and decreased urine output may be the only manifestations. However, prolonged hypoperfusion can cause acute tubular necrosis (ATN), which results in sloughing of renal tubular cells into the tubular lumen and obstruction. In addition, the production of Tamm-Horsfall proteins forms coarse granular casts, inciting an intense inflammatory response, further injuring the renal parenchyma (270,271). Other agents

Table 8.17 Visceral Proteins Utilized as Indicators for Nutritional Status during Nutritional Repletion

Protein	Normal Range	Half-Life (days)	Levels Low in	Levels High in
Albumin	3.5–5.4 g/dL	18	Liver disease, pregnancy, overhydration, nephrotic syndrome	Dehydration
Transferrin	200–400 mg/dL	8	Chronic infection, chronic inflammation, liver disease, iron overload, nephrotic syndrome	Iron deficiency, pregnancy
Prealbumin	20–40 mg/dL	2	Liver disease, inflammation, surgery, nephrotic syndrome	
Retinol-binding protein (RBP)	3–6 mg/dL	0.5	Liver disease, hyperthyroidism, zinc deficiency, nephrotic syndrome	Renal insufficiency

that can induce ATN include aminoglycoside antibiotics and iodinated contrast media. Approximately 15% of patients who receive aminoglycosides will have nephrotoxicity, and serum levels of these antibiotics need to be carefully monitored (272). Iodinated contrast media, used in multiple radiographic procedures, induces ATN by impairing nitric oxide production and increasing free radical formation (273,274). Diabetic patients with creatinine clearance rates less than 50 mL/minute are at particularly high risk (275).

The final reason for ARF in the postoperative gynecologic oncology patient is outflow obstruction. Because of the radical pelvic procedures performed by gynecologic oncologists, ureteral injury is possible and needs to be excluded early in the evaluation of patients with ARF. Prompt reversal of the obstruction can further limit renal damage.

In general, expected postoperative urinary output should be maintained at 0.5 mL/kg of weight per hour. Most oliguria can be treated with intravascular expansion in the first 24 to 48 hours postsurgery. Hypoperfusion of the renal parenchyma must be avoided to prevent ATN from occurring. The definition of ARF is not standardized, but includes rising serial creatinine measurements, urine output less than 400 mL/24 hours, or, in drastic situations, the initiation of dialysis (269). Once diagnosed, calculating the fractional excretion of sodium (FENa) or chloride can help to discern between prerenal causes or renal causes (hypoperfusions vs. ATN). The formula is presented below (269):

$$\text{FENa} = (\text{urine Na level} \times \text{serum Cr level}) / (\text{serum Na level} \times \text{urine Cr level}) \times 100\%$$

If the FENa is less than 1% and the urine specific gravity is greater than 1.025, the diagnosis is hypoperfusion. However, if ischemia has occurred, the FENa will be greater than 4% and the urine specific gravity will fall to 1.010 because of tubular damage and loss of renal concentrating mechanisms. One cannot calculate FENa in patients who have received diuretics or hyperosmotic agents (e.g., mannitol or contrast media). If prerenal and renal causes of low urine output have been excluded, ultrasonography may be useful in evaluating for outflow obstruction.

Once the underlying causes for HARI have been eliminated (e.g., hypoperfusion, obstruction, sepsis), only time can be offered as treatment. Therapies such as low-dose dopamine, furosemide, or mannitol administration, or atrial natriuretic peptide use have not demonstrated prevention of or improved recovery from HARI (276–281). Dialysis remains the only intervention that can support patients until return of renal function. Indications for dialysis include (a) hyperkalemia, metabolic acidosis, or volume expansion that cannot be controlled; (b) symptoms of uremia or encephalopathy; or (c) platelet dysfunction inducing a bleeding diathesis (269).

Shock

Definition

Shock is defined in its simplest terms as a decrease in tissue perfusion below the lowest metabolic needs of the tissue bed. This usually results in a depletion of stored energy and an increase in anaerobic metabolism with a buildup of lactic acid in addition to other toxic waste products. Hypotension is incorrectly thought of as a defining component of shock. Hypotension often leads to hypoperfusion, but the hypotensive patient is not in shock until evidence of hypoperfusion occurs. Various types of shock exist.

Hemorrhagic Shock

The first thought for a surgeon managing a postoperative patient who manifests signs and symptoms of shock is hemorrhage.

Hypovolemic shock secondary to inadequate preload can be the result of excessive or ongoing blood loss or inadequate replacement or both. Certainly, after radical debulking procedures or major extirpative procedures, the potential for postoperative hemorrhage exists. Tachycardia, hypotension, and oliguria are typical clinical signs. In the face of these clinical signs, the surgeon should have high suspicion for active bleeding and be preparing to return the patient to the operating room for correction. Measurement of hemoglobin or hematocrit can be normal in the setting of acute blood loss since a decrease in red cells is accompanied by a decrease in mass. Once fluid is given for resuscitation, dilution will occur and the hemoglobin/hematocrit will fall. With invasive monitoring, the CVP will be low, as will cardiac output and the PAOP. As the stroke volume decreases to inadequate amounts, the heart compensates by increasing the heart rate in order to maintain cardiac output. The treatment in these cases is aggressive volume resuscitation and control of ongoing blood loss. The controversy between resuscitation with colloid (albumin, plasma) or crystalloid (normal saline or lactated Ringer's solution) remains ongoing. The SAFE study is a large, randomized controlled double blind study that compared albumin to saline infusion in the intensive care unit. It failed to demonstrate a beneficial effect (282).

Endpoints of resuscitation include normalization of serum lactic acid and base deficit. Measurement of the base deficit via an arterial blood gas analysis has become an effective means for following response to resuscitation. Following large operations where patients are admitted to the ICU and where large, expected fluid shifts occur, the base deficit should be monitored serially until it has returned to normal. If a patient has a worsening base deficit (i.e., becomes more negative), then a search for other problems, such as ongoing hemorrhage, subacute anastomotic leak(s), or tissue ischemia, must be made and be addressed before the base deficit will normalize. The base deficit should normalize within the first 24 hours after surgery.

In the case of continued or rapid bleeding, the obvious course of treatment is reoperation. A number of options are now available intraoperatively in these situations. Obvious bleeders are controlled and ligated. Raw surfaces can be coagulated, treated with fibrin sealants or absorbable hemostatic powders. Damage-control packing has been shown to increase survival in the direst situations. Massive transfusion, defined as greater than 1.5 blood volumes, presents a number of additional problems. These patients will have a dilutional coagulopathy, hypocalcemia, and hyperkalemia. After 6 to 8 red blood cell transfusions have been given in rapid fashion for massive bleeding, some would advocate empiric fresh frozen plasma and platelets. Platelet transfusion is indicated for a platelet count <50,000 in the actively bleeding patient. The trauma literature supports the use of high product ratio during massive transfusion to improve mortality; however, this has yet to be demonstrated in the general surgical population (283). Attention to delivery of warm transfusions is critical as hypothermia and acidosis will promote coagulopathy and worsening in bleeding. Once any of the “lethal triad” (hypothermia, acidosis, and coagulopathy) is manifested then the operation needs to be quickly terminated even if this means damage-control packing and transport to an ICU setting.

Cardiogenic Shock

A patient with adequate preload who shows signs of poor perfusion secondary to poor cardiac output is categorized as being in cardiogenic shock. The etiology may be a decrease in contractility (secondary to myocardial infarction) or an increase in afterload (severe hypertension). Typically, “pump failure” results in decreased stroke volume and backup of fluid into the pulmonary circulation. This leads to pulmonary edema and decreased oxygen delivery. The most common provocation for pump failure is the over-administration of fluid in a patient with

compromised ventricular function. Treatment consists of diuresis and optimization of cardiac output without increasing myocardial oxygen demand (a difficult task). In the case where significant failure has led to hypotension, dopamine and dobutamine are usually the drugs of choice. The usage of these drugs was discussed previously. Digoxin is commonly used for increasing contractility, but its effects are minor in the acute setting. In addition to inotropic support, correction of electrolyte disturbances (particularly potassium, calcium, and magnesium), maintenance of proper systemic oxygen saturation, and analgesia are important factors in decreasing myocardial stress.

Septic Shock

Septic shock has commonly been defined as hypotension related to infection with eventual organ failure secondary to hypoperfusion despite adequate fluid resuscitation. This definition has changed with that of SIRS and is discussed in the section on “Sepsis and Systemic Inflammatory Response Syndrome” below. Sepsis is defined as a subset of patients with SIRS who have a documented infectious process. Resuscitation should be guided according to the recommendations in the Surviving Sepsis Campaign (284).

Infectious Disease Issues

Nosocomial Infections

Infections in the critically ill patient population are a significant cause of morbidity and mortality. Patients in the ICU are particularly vulnerable to infection because of decreased host defenses and the high incidence of resistant bacterial isolates found in ICU settings. In addition, the presence of indwelling catheters and intravenous lines lowers the inoculum needed to cause infection and provides portals of entry (285). Nosocomial infections are commonly associated with complications of medical or surgical therapy. Approximately 45% of ICU patients will have an infection and approximately half of those will have acquired the infection while in the ICU (285). Treatment includes identifying and eradicating the source of infection and promptly initiating empirical antibiotic therapy aimed at multi-drug-resistant gram-negative and gram-positive organisms. If an intra-abdominal or pelvic source is suspected, empiric antibiotic therapy should include anaerobic coverage. Appropriate antibiotic classes include carbapenems, extended-spectrum penicillins, fluoroquinolone-metronidazole, aminoglycoside-metronidazole, or clindamycin combinations (286). In Chapter 29, the management of infections in the gynecologic cancer patient is discussed; therefore, information here is limited to infections pertaining to the critically ill patient.

Fungal Infections

Systemic fungal infections are of great concern for severely ill patients and are linked to an increased risk of morbidity and mortality. Diagnosis of a systemic candidal infection is not based on a unique presentation and therefore can be difficult to definitively pronounce at onset. Although a positive blood culture is the gold standard for diagnosis, blood culture techniques are relatively insensitive and clinicians frequently must rely on clinical judgment about the probability that candidemia is responsible for a patient's symptoms. Patients who have persistent fever, hypothermia, or unexplained hypotension, despite broad spectrum antibiotic coverage, may have candidemia. Risk factors that have been associated with candidemia and invasive candidiasis include treatment with multiple antibiotics for extended periods, the presence of central venous catheters, the use of TPN, abdominal surgery, prolonged ICU stay, and compromised immune status (287). The initial choice of therapeutic

agents depends on the epidemiologic characteristics of the particular ICU and host factors such as the severity of illness, infection site(s), neutropenia, and organ dysfunction. Fluconazole has excellent activity against *Candida albicans*, but infections caused by *Candida glabrata* or *Candida krusei* must be treated with amphotericin B or caspofungin. Amphotericin B should not be used in patients with renal failure, and azoles and echinocandins (caspofungin) should be used with caution in patients with hepatic dysfunction. Antifungal therapy should be continued for 14 days past the first negative blood culture for candidemia or until clinical microbiological or radiographical resolution of the infection (288). In addition to antifungal therapy, it is generally recommended that all patients with candidemia have a dilated eye exam by an ophthalmologist and that all catheters be removed if possible (although tunneled catheters are at less risk) (287).

Abdominal Infections

The diagnosis of an intra-abdominal source of infection can be challenging in critically ill patients. Not all patients exhibit the same classic symptoms, as they may be masked by other disease processes or medical interventions. For example, abdominal pain and peritoneal signs may not be apparent in patients who are obtunded or sedated and ventilated. Fever and leukocytosis may be absent in 35% and 55% of patients with peritoneal infections (289). Ultrasonography is a useful diagnostic test that can be performed in the ICU and may assist with therapeutic intervention as well. It is extremely sensitive for evaluations of the pelvis and right upper quadrant, but evaluation of the entire abdomen can be limited by bowel gas, surgical dressings, and operator experience. For many of these reasons, a computed tomographic (CT) scan is the preferred study for the evaluation of patients with suspected intra-abdominal infection. To avoid misdiagnosing fluid-filled bowel as a possible abnormal fluid collection, it is essential that contrast agents be used when performing these studies. CT also has limitations, especially when used in the critically ill population. The presence of renal insufficiency precludes the use of intravenous contrast, and ileus or bowel obstruction may prevent complete opacification of the gastrointestinal tract. Diagnostic laparoscopy can be performed in the ICU with minimal anesthesia and is a safe, accurate, and cost-effective alternative to laparotomy when managing suspected intra-abdominal processes (290).

Once identified, an intra-abdominal abscess must be fully evacuated and the source controlled. Radiologically assisted percutaneous drainage has become the preferred method for treating most abscesses located in the abdomen and pelvis. For well-delineated unilocular fluid collections, percutaneous drainage has a success rate better than 80% (291). Percutaneous drainage of complex abscesses or those with an enteric communication has a lower success rate, but remains a reasonable alternative treatment for the high-risk patient (292).

In some cases, surgery may be the only appropriate lifesaving intervention. Timely laparotomy in the critically ill patient with diffuse peritonitis allows for peritoneal toilet, debridement of infected and necrotic tissue, and control or repair of the source. Laparoscopic drainage of complex intra-abdominal abscess has also been reported with good success rates (293). Complex intra-abdominal infections that cannot be effectively controlled by a single laparotomy may be managed best with an open-abdomen approach with temporary wound closure utilizing a composite, negative pressure (vacuum-pack) dressing (294). Potential advantages of the open-abdomen approach include facilitation of repeated debridement, effective drainage, repeat exploration of the peritoneal cavity (at the ICU bedside if necessary), and reduction in intra-abdominal pressure. In general, the intervention that accomplishes the source control objective with the least physiologic upset should be employed (295).

Sepsis and Systemic Inflammatory Response Syndrome

Inflammation is the body's initial response to tissue injury produced by chemical, mechanical, or microbial stimuli. Inflammation is an exceedingly complex cellular and humoral response involving interaction between the complement, kinin, coagulation, and fibrolytic cascades. The goal of inflammation is to enhance the movement of nutrients and phagocytic cells to the injury site in order to prevent invasion of microbes and limit the extension of injury. As a local response, this is beneficial, but appropriate regulation is necessary to prevent a pathologic, exaggerated systemic response, which is clinically identified as SIRS. Sepsis is the clinical syndrome of SIRS that is due to severe infection. The mediator response in SIRS can be divided into 4 phases based on the cytokine/cellular response: induction, triggering of cytokine synthesis, evolution of cytokine and coagulation cascade, and elaboration of secondary mediators leading to cellular injury. The three most important mediators operating in SIRS appear to be tumor necrosis factor- α (TNF- α), interleukin-1 (IL-1), and interleukin-6 (IL-6). The microcirculation endothelium is the key target for injury in the sepsis syndrome (296).

In 1992, the American College of Chest Physicians and the Society of Critical Care Medicine published definitions for SIRS and sepsis (Table 8.18) with the goal of standardizing terminology to aid clinicians in the diagnosis and treatment and to aid in the interpretation of research in this field (297). Many have criticized the 1992 consensus definitions as too nonspecific to be of use. In 2001, a group of experts reconvened and expanded the list of signs and symptoms of sepsis to reflect clinical bedside experience. In addition to the original criteria, altered mental status, oliguria, skin mottling, coagulopathy, hypoxemia, hyperglycemia in the absence of diabetes, thrombocytopenia, and altered liver function tests can also be used to establish the diagnosis of sepsis (298).

The host response, more than the pathogen, is the primary determinant of patient outcome. Failure to develop a fever, leukopenia, and hypothermia are associated with increased fatality rates in patients with sepsis and are thought to represent abnormalities in the host's inflammatory response. Other risk factors for mortality from sepsis include age greater than 40, underlying medical conditions, malnutrition, immune suppression, and cancer. The presence or absence of a positive blood culture does not influence outcomes; however, sepsis due to a nosocomial infection has a higher mortality than community-acquired infection (299).

Sepsis with acute organ dysfunction (severe sepsis) is a complex condition that represents a major challenge to the critical care team and carries a crude mortality rate of 28% to 50% (300).

Table 8.18	Definitions for Systemic Inflammatory Response and Sepsis (SIRS)
SIRS	Two or more of the following in the setting of a known cause of inflammation: Temperature $>38^{\circ}\text{C}$ or $<36^{\circ}\text{C}$ Pulse >90 Respirations $>20/\text{min}$ or $\text{Paco}_2 <32 \text{ mm Hg}$ WBC count $>12,000$ or $<4000 \text{ cells}/\text{mm}^3$ or $>10\%$ band forms
Sepsis	SIRS due to known infection
Severe sepsis	Sepsis with evidence of organ dysfunction, hypoperfusion, or hypotension
Septic shock	Sepsis with hypotension despite adequate fluid resuscitation

Source: Adapted from 1991 American College of Chest Physicians/Society of Critical Care Medicine Consensus Conference definitions, with permission.

Gram-negative and gram-positive organisms as well as fungi cause systemic sepsis and septic shock. Early recognition is crucial to patient survival because mortality rates are exceedingly high if the full clinical picture of shock and organ dysfunction develops. Septic shock is divided into an early hyperdynamic state and a late hypodynamic state.

Low systemic vascular resistance, splanchnic vasoconstriction, and increased cardiac output characterize the hyperdynamic phase of shock. Venous capacitance is increased and results in diminished effectiveness of the circulating blood volume. Aggressive volume resuscitation must be provided to restore cardiac preload and ventricular filling. These patients are best managed in an ICU with the placement of an arterial line, a PA catheter, and a bladder catheter. Appropriate cultures should be obtained and intravenous broad-spectrum antibiotics should be started within the first hour of recognition of severe sepsis. Laboratory tests of immediate concern include arterial blood gas determinations, creatinine, electrolytes, lactate, coagulation panel, and a complete blood count. Oxygenation and ventilation should be optimized with mechanical ventilation if indicated. If hypotension persists after optimization of the PCWP, the use of norepinephrine or dopamine may be necessary. Surgical debridement or manipulation of infected material should not be performed until the patient has been stabilized.

Early goal-directed therapy of the septic patient has been shown to improve survival. During the first 6 hours of resuscitation, the goals of therapy as outlined by the Surviving Sepsis Campaign guidelines include CVP of 8 to 12 mm Hg, mean arterial pressure ≥ 65 mm Hg, urine output $\geq 0.5 \text{ mL}/\text{kg}/\text{hour}$, and central venous or mixed venous oxygen saturation $\geq 70\%$. If during the first 6 hours oxygen saturation goals are not achieved despite appropriate CVP, then transfusion of red blood cells to achieve a HCT $>30\%$ and/or initiation of a dobutamine infusion is the next step (301).

In the hypodynamic phase of septic shock, hypotension results from cardiac output deterioration. The patient is often cool, mottled, oliguric, diaphoretic, and confused. The etiology of the hypodynamic cardiovascular response to sepsis may be inadequate volume resuscitation, underlying cardiac disease, or myocardial dysfunction associated with sepsis. This is a state of gross decompensation with global tissue hypoxia and is associated with greater mortality.

Numerous clinical trials have attempted to find specific agents that could modulate the underlying disease process in sepsis. Candidate therapies included agents that target mediators of inflammatory response, agents that boost the immune system, and prostaglandin inhibitors, but none was shown to be beneficial. One such agent, drotrecogin alfa (activated-Xgris[®]), is a recombinant form of human activated protein C, an endogenous protein with antithrombotic, pro-fibrinolytic, and anti-inflammatory properties that is frequently deficient in sepsis. Although initial studies (The Recombinant Human Activated Protein C Worldwide Evaluation in Severe Sepsis-PROWESS) showed a clinically significant reduction in the 28-day all-cause mortality rate due to severe sepsis (302), results from a subsequent trial, the PROWESS-SHOCK trial, failed to demonstrate any significant benefit in 28-day all-cause mortality. The drug was subsequently withdrawn from the market in October 2011 (303).

In addition to early goal-directed therapy with hemodynamic interventions that balance systemic oxygen delivery with oxygen demand, other management strategies have shown in randomized, controlled trials to reduce mortality associated with severe sepsis. These include limiting the tidal volume to 6 to 7 mL/kg ideal body weight for patients requiring mechanical ventilation for ARDS, the use of moderate-dose corticosteroids (hydrocortisone 200 to 300 mg and fludrocortisone 50 μg daily) for 7 days in patients with refractory septic shock, and maintaining serum glucose levels $<180 \text{ mg}/\text{dL}$ (301). These therapies are not mutually exclusive,

and optimal patient management may require a combination of approaches. Some of these strategies vary dramatically from traditional approaches and will require education and established protocols to safely incorporate them into practice.

Multiple Organ Dysfunction Syndrome

Multiple organ dysfunction syndrome (MODS) is defined as the development of progressive physiologic dysfunction of two or more organ systems after an acute threat to systemic homeostasis (297). An acute threat can include SIRS, sepsis, massive trauma, burns, ischemia, or reperfusion injury. Patients usually present with pulmonary dysfunction, which typically develops early in the course of SIRS or sepsis. Renal dysfunction will present as a prerenal azotemia unless the initial insult stimulated a sudden oliguric acute tubular necrosis. Hyperbilirubinemia is the earliest indication of hepatic dysfunction. Gastrointestinal abnormalities include ileus, stress ulcers, diarrhea, and mucosal atrophy. The platelet count has been used as a surrogate marker of the hematologic system. Cardiac function is often measured by the severity of hypotension or the need for vasopressors. Deterioration of the nervous system is manifested by encephalopathy and peripheral neuropathies. The treatment of MODS is support of individual organ function and aggressive therapies aimed at correcting the underlying process. Mortality is related to the number of dysfunctional systems and is greater than 80% once four organ systems fail (304).

The Acute Physiology and Chronic Health Evaluation (APACHE) provided population-based estimates of mortality for the day of ICU admission (305). Several versions of the APACHE scoring system have been utilized, most recently APACHE IV. Organ failure scores, such as the Sequential Organ Failure Assessment (SOFA), can help assess organ dysfunction over time and are useful to evaluate morbidity. Independent of the initial value, an increase of the SOFA score (Table 8.19) during the first 48 hours of an ICU admission predicts a mortality rate of 50% or greater, and improvement of cardiovascular, renal, or respiratory SOFA score from baseline through day 1 of ICU admission is significantly related to greater survival (306). It is important to note that these and other outcome

prediction models were designed as tools to be used in critical care research in order to stratify patients by severity of illness. They have not been validated for making decisions relating to individual patients.

Abdominal compartment syndrome (ACS) is an important but often unrecognized cause of acute deterioration of a patient after massive fluid resuscitation for septic or hypovolemic shock. Although ACS can impair the function of every organ system, it is generally manifested as hypotension, reduced urine output, and decreased pulmonary compliance. Most commonly associated with trauma patients, it has also been observed in patients with massive ascites, bowel obstruction or ileus, peritonitis, pancreatitis, and intraperitoneal blood. Intra-abdominal pressure (IAP) is usually measured indirectly by a balloon-tipped catheter in the bladder. Intra-abdominal hypertension is defined as an IAP of 12 mm Hg or greater recorded by a minimum of 3 standard measurements conducted 4 to 6 hours apart (307). ACS is defined by an IAP of 20 mm Hg or greater and single or multiple organ failure that was not previously present. Operative decompression of the abdominal cavity with maintenance of an open abdomen via use of temporary closure techniques such as a vacuum pack is the only treatment that reverses the physiological abnormalities resulting from ACS.

NEUROLOGIC ISSUES

Emotional and mental health of critically ill patients can affect their physical well-being, pain tolerance, and recovery. Stress and strain can be exacerbated by the unknown, pain, wounds, pre-existing disease, infection, invasive medical interventions, and routine nursing care such as airway suctioning, repositioning, or dressing changes. The restlessness and distress often associated with critical illness must be quelled with analgesia, sedation, and neuromuscular blockade as a last resort. The Society of Critical Care Medicine and American Society of Health-System Pharmacists (ASHP) clinical practice guidelines for sedation, analgesia, and neuromuscular blockade of the critically ill adult were revised in 2002. This comprehensive document is available online at www.ashp.org (308,309).

Table 8.19 The Sequential Organ Failure Assessment (SOFA) Score

Variables	SOFA score				
	0	1	2	3	4
Respiratory: PaO ₂ /FIO ₂ , mm Hg	>400	≤400	≤300	≤200 ^a	≤100 ^a
Coagulation: platelets × 10 ³ /μL ^b	>150	150	100	50	20
Liver bilirubin, mg/dL ^b	<1.2	1.2–1.9	2.0–5.9	6.0–11.9	>12.0
Cardiovascular hypotension	No hypotension	Mean arterial pressure <70 mm Hg	Dop ≤5 or Dob (any dose) ^c	Dop >5, Epi 0.1, or Norepi 0.1 ^c	Dop >15, Epi >0.1, or Norepi >0.1 ^c
Central nervous system, Glasgow Coma Scale score	15	13–14	10–12	6–9	<6
Renal creatinine, mg/dL or urine output, mL/d	<1.2	1.2–1.9	2.0–3.4	3.5–4.9 or <500	>5.0 or <200

Norepi, norepinephrine; Dob, dobutamine; Dop, dopamine; Epi, epinephrine; FIO₂, fraction of inspired oxygen; PaO₂, partial pressure oxygen.

^aValues are with respiratory support.

^bTo convert bilirubin from mg/dL to μmol/L, multiply by 17.1.

^cAdrenergic agents administered for at least 1 hour (doses given are in μg/kg per minute).

Analgesia

Pain management for critically ill patients is a universal goal for all involved in their care. Patients who are not satisfied with the treatment they receive for pain may become more stressed and irritable, sleep less, and have a poor opinion of the care they are receiving on the whole. Pain may contribute to pulmonary dysfunction through localized guarding and generalized muscle rigidity that restricts movement of the chest wall and diaphragm. Unrelieved pain also evokes a stress response characterized by tachycardia, increased myocardial oxygen consumption, hypercoagulability, immunosuppression, and persistent catabolism (310). The combined use of effective analgesia and sedation may ameliorate the stress response and diminish pulmonary complications in postoperative critically ill patients. A comprehensive overview of pain management is covered in Chapter 32; therefore, only key aspects of pain management applicable to patients in the ICU will be addressed.

Pharmacologic therapies include opioids, NSAIDs, and acetaminophen. ASHP guidelines recommend fentanyl, hydromorphone, and morphine given as a continuous infusion or scheduled doses rather than “as needed.” Fentanyl has the most rapid onset and shortest duration, but repeated dosing may cause accumulation and prolonged effects. Fentanyl may also be administered via a transdermal patch to hemodynamically stable patients with more chronic analgesic needs, but it is not recommended for the management of acute pain. Morphine has a quick onset but longer duration of action, so intermittent doses may be given. However, morphine causes histamine release, which contributes to hypotension, especially in a hemodynamically unstable patient. Hydromorphone’s duration of action is similar to morphine but lacks an active metabolite or histamine release, making it an ideal drug for continuous infusion and for use in patients who cannot tolerate hypotension. Meperidine has an active metabolite that causes neuroexcitation including apprehension, tremors, delirium, and seizures, so its use is not recommended in critically ill patients who may need repeated doses. The characteristics of analgesics and sedatives commonly used in ICU patients are summarized in Table 8.20.

Sedation

To further combat anxiety and agitation associated with hospitalization and pain, sedatives are commonly added to routine medication administration. The physical environment of the ICU, limited ability to communicate, sleep deprivation, and medical circumstances precipitating the ICU admission are contributing factors creating anxiety in critically ill patients. Efforts to reduce anxiety, including frequent reorientation, provision of adequate analgesia, and optimization of the environment, may be supplemented with sedatives. Agitation is also common in ICU patients; however, not all patients with anxiety will exhibit agitation. Sedatives reduce the stress response and improve tolerance to routine ICU procedures. For example, the use of sedation medication may be necessary to facilitate mechanical ventilation. Generally, sedatives should be administered intermittently to determine the dose needed to achieve the sedation goal, but they may be given as a continuous infusion if necessary. Daily interruption of sedative infusion is associated with shorter duration of mechanical ventilation, shorter ICU stays, and fewer instances of posttraumatic stress disorder (311,312). Benzodiazepines are sedatives and hypnotics that cause anterograde amnesia but lack analgesic properties. Midazolam has a rapid onset and short duration of effect with single doses, making it ideal for treating acutely agitated patients or for brief sedation with invasive procedures. Lorazepam has a slower onset but fewer potential drug interactions because of its metabolism via glucuronidation (Table 8.20).

Propofol is an intravenous general anesthetic that has sedative and hypnotic properties at lower doses. Like the benzodiazepines, propofol has no analgesic properties. Propofol has a rapid onset and short duration of sedation once discontinued. Propofol is a phospholipid emulsion that provides 1.1 kcal/mL from fat and should be counted as a caloric source. Long-term infusions may result in hypertriglyceridemia and monitoring is recommended after 2 days of use (308). Physiologic dependence and potential withdrawal symptoms have been described in ICU patients who have been exposed to more than 1 week of sedative or narcotic therapy, including the use of propofol (313).

Table 8.20 Characteristics of Selected Analgesics and Sedatives Frequently Used in Critically Ill Patients

Agent	Indication	Active Metabolites (Effect)	Adverse Effects	Intermittent Dose (IV) ^a	Infusion Dose Range
Fentanyl	Pain	No metabolite, patient accumulates	Rigidity with high doses	0.35–1.5 µg/kg q 0.5–1 h	0.7–10 µg/kg/h
Hydromorphone	Pain	None	—	10–30 µg/kg q 1–2 h	7–15 µg/kg/h
Morphine	Pain	Yes (sedation)	Histamine release	0.01–0.15 mg/kg q 1–2 h	0.07–0.5 mg/kg/h
Ketorolac	Pain	None	GI bleeding, renal	15–30 mg q 6 h; decrease if >65 yr; avoid >5 day use	—
Midazolam	Acute agitation	Yes (prolonged sedation)	—	0.02–0.08 mg/kg q 0.5–2 h	0.04–0.2 mg/kg/h
Lorazepam	Sedation	None	Solvent-related acidosis/renal failure in high doses	0.02–0.06 mg/kg q 2–6 h	0.01–0.1 mg/kg/h
Propofol	Sedation	None	Elevated triglycerides	—	5–80 µg/kg/min
Haloperidol	Delirium	Yes (EPS)	QT interval prolongation	0.03–0.15 mg/kg q 0.5–6 h	0.04–0.15 mg/kg/h

EPS, extrapyramidal symptoms; GI, gastrointestinal; IV, intravenous.

^aMore frequent doses may be needed for acute management in mechanically ventilated patients.

Neuromuscular Blockade

Neuromuscular blocking agents (NMBAs) can be used in conjunction with sedatives to facilitate mechanical ventilation, to manage intracranial pressure in head trauma, to ablate muscle spasms, and to decrease oxygen consumption only when all other means to accomplish these aims have failed (309). Pancuronium is a long-acting NMBA that is effective for up to 90 minutes after intravenous bolus dose of 0.06 to 0.1 mg/kg. It can be used as a continuous infusion by adjusting the dose to the degree of neuromuscular blockade that is desired. Since pancuronium is vagolytic, 90% of patients will have an increase in heart rate of greater than 10 beats per minute. For patients who cannot tolerate an increase in heart rate, vecuronium can be used. If neuromuscular blockade is necessary for patients with significant hepatic or renal failure, cisatracurium or atracurium should be used. Patients receiving any NMBA should be assessed using electronic twitch monitoring with a goal of adjusting the blockade to achieve 1 or 2 twitches. Before initiating neuromuscular blockade, patients should be adequately medicated with sedative and analgesic drugs, as it is difficult to assess pain and anxiety after NMBAs are given. Furthermore, neuromuscular paralysis without sedation is an extremely frightening and unpleasant experience.

Acute quadriplegic myopathy syndrome, also referred to as postparalytic quadriplegia, is a clinical triad of acute paresis, myonecrosis with increased creatine phosphokinase concentration, and abnormal electromyography that is related to prolonged exposure to NMBAs. This is a devastating complication of NMBA therapy and one of the reasons that indiscriminate use of these agents is discouraged. Increased risk of acute quadriplegic myopathy is associated with the concurrent use of corticosteroids; drug “holidays” may decrease the risk (314).

ICU Syndrome/Delirium

First reported in the 1960s, the term ICU syndrome, or psychosis, refers to a multitude of psychological disturbances exhibited by many critically ill patients (315). It has also been labeled postoperative delirium. The ICU syndrome has been defined as an altered emotional state occurring in a highly stressful environment that may manifest itself in a variety of psychological reactions including fear, memory disturbance, anxiety, confusion, withdrawal, despair, agitation, and disorientation. Factors such as sleep deprivation, noise, constant light exposure, restriction of movement, limited ability to communicate, as well as the patient's preadmission mental state and coping ability have all been reported as contributing causes of ICU syndrome. Current medical literature challenges this concept and argues that what is being called ICU syndrome or psychosis is diagnostic of delirium and not due to the ICU environment per se. Concerns have been raised that using the term *ICU syndrome* implies that confusion can be expected in the ICU setting and may reduce the vigilance necessary to recognize delirium and identify and treat the physiologic disturbances leading to it (316). Delirium is found in as many as 80% of critically ill patients and is associated with longer ICU admissions and increased mortality (317,318).

Delirium in the ICU setting is commonly caused by metabolic disturbances, hypoxia, electrolyte imbalances, alcohol or drug withdrawal, acute infection, and medications (Table 8.21) (316,318). Many drugs have anticholinergic properties that can exert an additive effect, causing neurotoxicity, especially in elderly patients. Anticholinergic-related delirium can be differentiated from other causes of delirium if the mental status clears after administration of the cholinesterase inhibitor physostigmine. Delirium presents in both a hypoactive and hyperactive form. Hypoactive delirium, which is associated with the worst prognosis, is characterized by psychomotor retardation, represents more global cerebral dysfunction, and is

Table 8.21 Commonly Used ICU Drugs Associated with Delirium^a

Anesthetics	Anticonvulsants	Atropine ^b
Lidocaine	Carbamazepine	Cimetidine ^b
Propofol	Phenobarbital	Corticosteroids ^b
	Phenytoin	Digoxin ^b
Antibiotics		
Amphotericin B	Antihypertensives	Narcotic analgesics
Aztreonam	Diltiazem	Fentanyl
Cephalosporins	Enalapril	Meperidine ^b
Ciprofloxacin	Hydralazine	Morphine
Doxycycline	Methyldopa	
Imipenem	Propranolol	Nitroprusside
Metronidazole	Verapamil	Phenylephrine
Penicillins		Procainamide ^b
Tobramycin		Scopolamine ^b
		Tricyclic antidepressants ^b

^a Listing is not intended to be all inclusive.

^b Drugs known to have significant anticholinergic properties.

manifested by a calm appearance, inattention, and obtundation in extreme cases. Hyperactive delirium is more easily recognized by agitation and combative behaviors. Elderly patients may pose a particular diagnostic challenge when delirium is superimposed on baseline dementia.

The medical management of delirium consists of finding and treating underlying medical conditions and then controlling any behavioral disturbances if necessary. Neuroleptic drugs are the first-line agents for the treatment of delirium. When causes are related to alcohol withdrawal syndrome, management is with benzodiazepines. Haloperidol is the neuroleptic of choice because it has minimal anticholinergic or hypotensive effects. A dose of 2 to 10 mg intravenously can be given every 20 to 30 minutes until agitation resolves. Once the delirium is controlled, scheduled doses every 4 to 6 hours consisting of 25% of necessary loading doses can be used and tapered off over several days. A continuous infusion can also be used (Table 8.20). Patients receiving repeat doses of haloperidol should be monitored for electrocardiographic changes. Extrapyrimal side effects such as rigidity, tremor, or facial tics can be managed with diphenhydramine hydrochloride (308).

End of Life Considerations

Despite valiant efforts and adherence to best practices of care, patients, families, and health care professionals are often faced with the difficult decision to withdraw life-sustaining treatment and care. The ethical aspect of foregoing treatment resides in the legal and ethical right of the patient to self-determination. Unfortunately, the majority of critically ill patients are unable to speak for themselves when decisions need to be made to withhold treatment. Living wills, power of attorney status, and advance directives must be acknowledged and honored regarding end of life considerations. If a medical power of attorney is not in place, some states stipulate who the surrogate will be by a legal hierarchy. The ethical basis for identification of an appropriate surrogate is primary if none of the preceding legal bases apply. In this situation, the physician and other health care providers

have the responsibility to help identify the person or persons who have knowledge of the patient's values and preferences in order to assist with medical decisions on the patient's behalf. This process can become difficult in circumstances when family members or others close to the patient are in disagreement as to who should be the surrogate or what the patient would prefer. In these cases, health care providers should be knowledgeable of applicable legal directives and their ethical responsibility to act in their patient's best interest. Consultation with the institution's ethics committee may be helpful in trying to reach consensus (319). Although not responsible for the patient's death, those close to the patient often are left with feelings of guilt and anxiety in addition to their bereavement. It is important that the health care providers support the family both before and after the decision to withhold or withdraw life-sustaining treatment has been made, not imparting any personal bias.

End-of-life care of patients in the ICU requires a dramatic paradigm shift in attitude and interventions from intensive rescue-type care to intensive palliative care. When considering the array of interventions that may be discontinued or held, physicians and surrogates should focus on clearly articulating the

goals of care. For example, a goal for survival until the patient's important loved ones can gather to say their good-byes may justify short-term continuation of ventilator support. If the only goal is patient comfort, then such treatment should be stopped. The withdrawal of life-sustaining treatment is a clinical procedure that deserves the same preparation and expectation of quality as other medical procedures. Honest, caring, and culturally sensitive communication with the patient's loved ones and the patient, if competent, should include explanations of how therapies will be withdrawn, what symptoms are expected, strategies to assess and ensure the patient's comfort, and information about the expected survival after interventions are withdrawn. Informed consent should be documented along with a formulated plan for withdrawing care (320). Adequate analgesia and sedation should be prescribed to relieve symptoms of pain, dyspnea, and anxiety during the dying process. Intravenous opioids and shorter acting benzodiazepines are the drugs of choice. The clinician's primary goal should be to prevent suffering and ensure the patient's comfort even if doing so unintentionally hastens the patient's death. For this reason, palliative care teams might be useful (320).

Surgical Principles in Gynecologic Oncology

DENNIS S. CHI ■ ROBERT E. BRISTOW ■ DAVID CIBULA

The management of most human cancers involves multimodal therapy, and this is especially true for female genital malignancies. Although some early gynecologic cancers can be eradicated by surgery alone, and chemotherapy as a single modality can often cure gestational trophoblastic malignancies, the optimal treatment for the majority of gynecologic malignancies requires surgery combined with chemotherapy and/or irradiation.

In this chapter, surgery is discussed both as a separate discipline and as an integral part of multimodal therapeutic planning. Although specific operations and relatively new surgical techniques are described for some disease sites, many procedures are addressed more completely in surgical texts and atlases to which the reader is referred (1–3). The role of surgical intervention in the treatment of gynecologic cancers is addressed herein with a more philosophic approach than would be taken in a surgical atlas. However, select illustrations and tips are included that have enabled us to approach various radical procedures more confidently and safely. The major goal of this chapter is to give the reader an appreciation and understanding of the surgical principles of the subspecialty of gynecologic oncology.

TECHNICAL ASPECTS OF SURGERY

Many physicians who practice the art and science of surgery tend to focus on the technical craft of the specialty only when teaching young surgeons. At other times, we are acutely aware that the most difficult part of our practice is the decision of whether or not to utilize surgical therapy. Preoperative and postoperative management is also demanding since therapy must be tailored for individual patients depending not only on their specific disease but also on their overall medical status. Owing to the significance of these pressing issues, we often take for granted the many years of preparation and experience in the craft of surgery.

Mastering the skills of surgery involves a thorough understanding of proper technique. It also requires frequent and consistent practice to keep surgical maneuvers well honed. For the student, this means actual practice in tying knots, manipulating instruments, and suturing. For the accomplished surgeon, it means that a sufficient case load must be maintained to ensure adequate practice of the technical art of the specialty. The surgeon should also keep abreast of new suture materials, instruments, and technical developments.

Anatomy

There is no substitute for a detailed knowledge of the anatomy of the pelvis and abdomen. The physician who pursues gynecologic

oncology as a career must be completely familiar with the pelvis, abdomen, retroperitoneum, and the lymphatic drainage of the female genital tract. No amount of surgical skill or knowledge of cancer therapy can compensate for the lack of this knowledge.

Lymphatic drainage from the cervix follows the uterine arteries and cardinal ligaments to the pelvic lymph nodes that include the external iliac, internal iliac (hypogastric), and obturator node groups (Fig. 9.1). From these pelvic lymph nodes, the drainage proceeds superiorly through the common iliac and presacral lymph nodes and then up to the paraaortic nodes.

The lymphatic drainage from both the uterine corpus and the ovaries follows one of three routes (Fig. 9.1): (a) along the uterine arteries in the broad ligaments to the pelvic nodes, (b) in channels following the round ligaments to the inguinal lymph nodes, or (c) along the ovarian lymphatics in the infundibulopelvic ligaments directly up to the paraaortic nodes.

The anatomy of the paraaortic lymph nodes has been well described by Fowler and Johnson (4). The paraaortic lymph nodes are part of the lumbar lymph node group. Usually, six subgroups of retroperitoneal nodes in the paraaortic region are recognized: paracaval, retrocaval, interaorto-caval, preaortic, paraaortic (left side), and retroaortic. The preaortic group drains the abdominal part of the gastrointestinal tract down to the mid rectum, whereas the retrocaval and retroaortic groups have no special area of drainage. The paracaval, interaorto-caval, and paraaortic (left side) nodes receive lymphatic drainage from the iliac lymph nodes, ovaries, and other pelvic viscera (apart from the alimentary tract), and therefore it is these groups of nodes that are sampled in the surgical staging of gynecologic malignancies. However, systematic paraaortic lymphadenectomy should address all major regions, including paracaval, retrocaval, interaorto-caval, preaortic, paraaortic, and retroaortic nodes.

There are typically 15 to 20 paracaval and paraaortic nodes per side. They are located adjacent to the inferior vena cava (IVC) and aorta, anterior to the lumbar spine, extending bilaterally to the medial margins of the psoas major muscles, and up to the diaphragmatic crura (4). The paracaval and paraaortic nodes usually dissected in gynecologic oncology span the region from the aortic bifurcation up to either the inferior mesenteric artery (IMA) or the renal veins.

The first major blood vessel encountered during a caudad-to-cephalad paraaortic node dissection is the IMA (Fig. 9.1). The IMA originates from the anterior surface of the aorta, approximately 3 to 4 cm above the aortic bifurcation. Next, the right and left ovarian arteries arise from their respective sides of the aorta, about 5 to 6 cm above the bifurcation (Fig. 9.1). The right ovarian vein inserts into the right side of the inferior vena cava (IVC), approximately 1 cm below the right renal vein. The left ovarian vein does not insert directly into the IVC, rather follows a path close to the left ureter inserting into the left renal vein lateral to

FIGURE 9.1. The pelvic and paraaortic lymph nodes and their relationship to the major retroperitoneal vessels.

the left border of the aorta. Three to four pairs of lumbar arteries and veins arise from the posterior surfaces of the aorta and IVC, respectively.

The gynecologic oncologist who operates on patients with advanced ovarian carcinoma often encounters disease being spread across upper abdominal structures such as the diaphragm, liver, pancreas, and spleen. Debulking of tumor from these areas has been demonstrated to improve the rate of optimal cytoreduction and subsequent survival (5,6). Anatomic considerations for diaphragm surgery include the relevant hepatic attachments and the underlying central vasculature (7,8) (Fig. 9.2). The anterior hepatic attachment is the falciform ligament, which contains the ligamentum teres in its infrahepatic portion, and attaches the liver to the anterior abdominal wall in its membranous hepatic portion. As the falciform ligament continues superiorly, its peritoneal surface divides laterally on each side to form the anterior right and left coronary ligaments. These coronary ligaments reflect off the liver capsule and delineate the posterior extent of peritoneum covering the superior diaphragm. The IVC lies to the right side of this falciform ligament division. The right and left hepatic veins drain into the anterior surface of the IVC at the level of this peritoneal reflection. The anterior coronary ligaments continue laterally and inferiorly along the posterior liver edge, where they join the posterior right and left coronary ligaments to form the right and left triangular ligaments, respectively. The right triangular ligament reflects from the liver to the diaphragm, right kidney, and right adrenal gland. The left triangular ligament

reflects primarily to the diaphragm; the posterior left coronary ligament lies higher than the esophageal hiatus and the esophagus is generally not encountered. The coronary ligaments on each side delineate the larger “bare area” of the liver on the right and a smaller “bare area” on the left, which underlie the central tendon of the diaphragm. The right phrenic nerve penetrates this central tendon lateral to the vena caval foramen on the right and is usually not encountered until the “bare area” is exposed. The left phrenic nerve may penetrate the left diaphragm muscle above the central tendon and is a consideration during left-sided anterior diaphragm surgery.

In the left upper quadrant of the abdomen, the spleen lies under the 9th, 10th, and 11th ribs. It is situated adjacent and slightly deep to the stomach and colon, lateral to the pancreas, and sits on the superior aspect of the left kidney. The posterior aspect of the spleen is in contact with the adrenal gland as well as Gerota’s fascia of the kidney. The tail of the pancreas often approaches the splenic hilum and sometimes contacts the spleen. The spleen varies in size between individuals, but in general measures 12 cm in length, 7 cm in width, and 3 to 4 cm in depth. The peritoneum creates folds that form the suspensory ligaments of the spleen. The four main “suspensory” ligaments are gastrosplenic, splenorenal, splenophrenic, and splenocolic ligaments. The splenophrenic and splenocolic ligaments are avascular. The gastrosplenic ligament contains the short gastric vessels. The splenorenal ligament has an anterior and posterior aspect and surrounds the splenic hilum. The splenic hilum contains the splenic artery, splenic vein, and

FIGURE 9.2. Peritoneal reflections of the liver: the lesser omentum (hepatogastric and hepatoduodenal ligaments) and its relation to the coronary ligament of the liver and diaphragm.

Source: Reprinted with permission from Skandalakis JE, Gray SW, Rowe JR, eds. *Anatomical Complications in General Surgery*. New York, NY: McGraw-Hill; 1983.

sometimes the tail of the pancreas. The splenic vessels sometimes branch before entering the spleen. The splenic artery is tortuous and is one of the three branches of the celiac trunk. It runs along the superior aspect of the pancreas and gives rise to the short gastric arteries prior to entering the spleen, which course in the gastrosplenic ligament and supply the portion of the greater curvature of the stomach, superior to the splenic artery (Fig. 9.3) (9). The splenic artery also gives rise to the left gastroepiploic artery, which supplies the remainder of the greater curvature of the stomach and the gastrocolic omentum. The splenic vein is slightly inferior and follows the course and branching of the artery.

Patient Positioning

Patient positioning for radical gynecologic oncology procedures is often critical in improving exposure, particularly in obese patients. For most women undergoing radical hysterectomy, ovarian cancer cytoreduction, or pelvic exenterative procedures, we prefer the low lithotomy position using Allen stirrups (Fig. 9.4) (1). The buttocks should extend 2 to 3 cm over the end of the table. This position allows simultaneous access to the perineum and abdomen. The weight of the leg should be on the foot with the legs well padded and attention paid to prevent pressure on the calf and the peroneal nerve. To further improve pelvic exposure, a blanket or pad can be placed under the small of the back.

Abdominal Incisions

Abdominal incisions in gynecologic oncology vary with the indication for the procedure, associated preoperative conditions (such as the presence of ascites or bowel obstruction), suspicion of upper abdominal pathology, and the presence of a previous abdominal scar. Incisions for surgery for gynecologic oncology patients should be highly individualized. Three basic incisions are used for

intraoperative exposure (Fig. 9.5) (2). Additionally, extraperitoneal access to the pelvic and paraaortic nodes can be achieved through a J-shaped incision (10) or a “sunrise” incision (11).

Transverse incisions offer the advantages of being the best cosmetic incisions for pelvic surgery while also being the least painful, resulting in less interference with postoperative pulmonary function. In addition, compared to vertical incisions, transverse incisions are allegedly stronger and allow better exposure to the pelvic sidewalls. Many gynecologic oncologists use transverse incisions when performing a radical hysterectomy or pelvic exenteration.

In performing the Maylard incision, it is recommended that the deep inferior epigastric vessels be isolated, sectioned, and ligated prior to dividing the rectus muscle (Fig. 9.6) (2). Occasionally, the pelvic surgeon will make a Pfannenstiel incision and find it inadequate. When more exposure is needed, the appropriate maneuver is to convert the Pfannenstiel to a Cherney-type incision. This conversion can be accomplished by dissecting the rectus muscles from the pyramidalis muscles and the anterior rectus sheath, and then transecting the rectus tendons at their insertion into the pubic bone.

Lymph Node Dissection

The surgical technique used to dissect the pelvic and paraaortic lymph nodes involves either a transperitoneal or extraperitoneal approach. The approach utilized is generally dictated by the primary site of disease and the planned accompanying procedure. In cases of endometrial and ovarian carcinoma where the anticipated procedure includes a hysterectomy and/or surgical debulking, the approach is invariably transperitoneal. However, in the pretreatment surgical staging of patients with advanced-stage cervical cancer, the transperitoneal approach has been associated with significant radiation-induced intestinal morbidity due to postoperative adhesion formation (12). Therefore, current clinical trials that require pretreatment surgical staging recommend that

the lymph node sampling be performed via the extraperitoneal approach or by operative laparoscopy (13).

Pelvic Lymph Node Dissection

Whether a transperitoneal or extraperitoneal approach is used, the pelvic lymphatic basin can be divided into 5 specific anatomical regions. Most surgeons initially remove pelvic nodes from the *external iliac region*. Lymphatic-fatty tissue is removed cranially, laterally, and medially from both external iliac vessels and between them. The medial border is formed by the paravesical space. The lateral border is the psoas muscle, the ventral is commonly indicated as the origin of the deep circumflex iliac vein, and the cranial border is the level of the common iliac artery bifurcation, where the lymphatic trunk continues as the superficial common iliac region (Fig. 9.7) (2). The genitofemoral nerve courses laterally to the external iliac artery and should be identified and preserved prior to excising the lymphatic tissue. It usually forms two branches, one running on the surface of the

FIGURE 9.5. Entry into the abdominal cavity can be made by three basic incisions: (1) the midline incision; (2) the transverse Maylard-type incision from anterior–superior iliac spine to anterior–superior iliac spine; and (3) the Pfannenstiel incision. The latter is not an incision for radical pelvic surgery, but it can be converted to a Cherney-type incision for improved exposure. For the patient who has some type of transverse incision, and for whom later exposure of the upper abdominal cavity is necessary, a midline upper abdominal incision can be separately used.

FIGURE 9.6. The Maylard incision. A transverse incision has been made from the anterior-superior iliac spine to the opposite anterior-superior iliac spine. The fascia has been incised transversely. The deep inferior epigastric vessels are located on the lateral and posterior borders of the rectus muscle. They are bluntly dissected from this position by the finger of the operator; isolated, clamped, sectioned, and tied. Only after they are tied should the rectus muscle be incised. This can be done with the Bovie.

psoas muscle and another through the lymphatic tissue on the external iliac vessels, where it can be easily cut or injured.

Mobilization and retraction of the external iliac vessels allows access to the *obturator region*. The cranial border is formed by the common iliac vessels bifurcation, where the lymphatic trunk continues cranially as the deep common iliac region. The medial anatomical border is the paravesical space and the ventral border is formed by the pubic bone together with levator ani and obturator muscles, where the obturator nerve leaves the pelvis through the obturator canal. The lateral border is formed by the obturator internal muscle and the caudal anatomical landmarks are the obturator vessels. The obturator nodes are most easily teased away from the nerve and vessels if one begins the dissection caudally (Fig. 9.8) (2). Usually the last dissected area is the *internal iliac region*, where the tissue is removed medially from the internal iliac vein.

The dissection continues cranially to the *common iliac region*. Tissue is removed ventrally and laterally from both common iliac vessels. The lymphatic tissue can be anatomically divided into two parts, the superficial one, which continues mostly from the external iliac region, and the deep one, which runs deeply between the common iliac vein and psoas muscle, continuing from the obturator region. The cranial border is the level of the aorta bifurcation. The genitofemoral nerve should be preserved as it lies on the surface of the psoas muscle. Deeply below the common iliac vessels and the psoas muscle, on the sacral bone, can be identified two nerve structures—the cranial part of the lumbosacral trunk (L4 + L5) (medially) and the obturator nerve (laterally), which enters the region from under the psoas muscle.

If presacral nodes are to be removed, the fatty-lymphatic tissue is removed above the sacral bone, below and between both common iliac veins. The caudal border is indicated by the level of right common iliac vessels bifurcation, where it continues caudally as the internal iliac region. Major branches of the inferior nerve hypogastric plexus should be preserved, as the plexus runs medially on both sides, below the ureters, inside of the mesoureter, which forms a thin layer of tissue between the medial pararectal fossa and large vessels.

FIGURE 9.8. A vein retractor is used to retract the external iliac veins anterior and lateral to expose the obturator space. Lymphatic tissue is gently teased from the psoas muscle. The entire lymphatic bundle is clamped, sectioned at its caudal end, and ligated at the pelvic sidewall. With the use of the Singley forceps, the lymphatic bundle is bluntly dissected from the obturator nerve and mobilized superiorly. Often, the obturator vein and artery must be sacrificed to obtain access to tissue posterior and lateral to the nerve. Once the tissue is mobilized superiorly, all areolar tissue is cleaned off the hypogastric vessels to the level of the bifurcation of the common iliac artery. The large tissue bundle is clamped and removed en bloc. A tie or clips may be used at the level of the bifurcation.

Transperitoneal Approach to the Paraaortic Nodes

The transperitoneal approach to the paraaortic lymph nodes can be accomplished by either the direct or the lateral approach. With the direct approach, the dissection begins with an incision in the peritoneum directly over the common iliac arteries and aorta. The lateral approach starts with an incision in the lateral paracolic gutters with subsequent medial reflection of the right and/or left colon. The advantage of the direct approach is that it involves less dissection of the intestine and ureter, whereas one of its main disadvantages is that it is associated with a greater degree of difficulty in exposing the left paraaortic nodes. Consequently, many surgeons sample the right paraaortic (paracaval) lymph nodes via the direct approach and use the lateral approach for the left-sided nodes.

With the direct approach to the right paraaortic nodes, an incision is made in the peritoneum overlying the right common iliac artery (Fig. 9.9). The incision is carried up over the aorta to the level of the duodenum. If the nodal dissection is to be carried out only to the level of the IMA, the duodenum may not need to be mobilized. Using blunt dissection, the ureter and ovarian vessels are identified and mobilized laterally. The lymphatic tissue lateral to the right common iliac artery is elevated and the caudal end is clipped and divided. The dissection then proceeds in a caudad-to-cephalad direction. A plane is created between the IVC and the lymphatic pedicle. The majority of the right paraaortic nodes overlie the IVC and they are generally easily dissected off the vessel. However, there is a fairly constant small

FIGURE 9.9. The small bowel is elevated out of the pelvis placing the mesentery on gentle traction. The right ureter and common iliac artery are identified and the peritoneum overlying the artery is incised.

vein within the lymphatics anterior to the IVC that inserts just above its bifurcation. If care is not taken to identify and ligate this so-called “fellow’s” vein early in the dissection, it can easily be torn with resultant heavy bleeding (1). When the most cephalad extent of the dissection is reached, the pedicle is clipped or coagulated and divided (Fig. 9.10).

If the nodes above the IMA need to be sampled, the third portion of the duodenum is mobilized by bilaterally incising the peritoneum around it and then sharply dissecting the areolar tissue underneath (4). The superior portion of the peritoneal incision can be carried up as high as the ligament of Treitz, which can also be divided if needed. Inferiorly, the peritoneal incision is extended over the right ureter around the cecum and up along the right paracolic gutter to mobilize the small bowel mesentery and part

FIGURE 9.10. The specimen is dissected in a cephalad direction. Hemostatic clips are used on either side of the developing pedicle as it is mobilized and divided, and also at the most cephalad extent of the dissection before the specimen is removed.

FIGURE 9.11. Extended peritoneal incision. The peritoneal incision is extended over the right ureter around the cecum and cephalad along the right paracolic gutter. This allows for mobilization of the small bowel mesentery as well as the ascending colon. Source: Reprinted with permission from Fowler JM, Johnson PR. Transperitoneal para-aortic lymphadenectomy. *Oper Tech Gynecol Surg* 1996;1:9.

of the right colon (Fig. 9.11) (4). The small bowel can then be packed into the upper abdomen or completely removed from the peritoneal cavity and stabilized outside of the abdominal cavity or put into a bowel bag outside the abdomen. The duodenum is retracted superiorly, allowing identification and ligation of the right ovarian artery and vein. The lymphatic tissue can then be safely dissected off of the right side of the aorta and the anterior surface of the IVC up to the level of the renal veins.

The left paraaortic lymph nodes may be removed through the same peritoneal incision. Sharp dissection is used to identify the left common iliac artery, left side of the aorta, IMA, left ureter, and left psoas muscle (Fig. 9.12). The ureter is again mobilized laterally. The lymphatic tissue lateral to the left common iliac artery and aorta is then removed in a caudad-to-cephalad direction. The left paraaortic lymph nodes lie lateral and partially behind the aorta. In dissecting these nodes, judicious use of vascular clips or the use of electrocautery will help prevent troublesome bleeding from the lumbar vessels. Safe removal of the lymph nodes above the IMA frequently requires identification and division of the left ovarian artery and vein, and occasionally ligation of the inferior mesenteric artery.

To remove right-sided paraaortic nodes via the lateral approach, the right paracolic gutter is incised along the line of Toldt (Fig. 9.13). The peritoneum is elevated off the psoas muscle and the incision is extended up to the hepatic flexure of the colon. Using sharp and blunt dissection, the right colon is reflected medially. The ureter and ovarian vessels can be identified attached to the undersurface of the reflected peritoneum. They may be left attached or mobilized laterally for better exposure. Further medial mobilization of the colon exposes the IVC and aorta. With the essential structures identified, the lymphatic tissue can then be dissected as previously described

FIGURE 9.12. Removal of the left paraaortic nodes through the same peritoneal incision. The dissection also proceeds in a cephalad direction, again using hemostatic clips on the lateral and medial margins. Care should be taken to avoid injury to the inferior mesenteric artery that arises approximately 3 to 4 cm above the aortic bifurcation.

FIGURE 9.13. The right paracolic gutter is exposed by medial traction on the ascending colon. The gutter is incised along the line of Toldt.

in a caudad-to-cephalad direction up to the third portion of the duodenum (Fig. 9.14).

If the lymph nodes above the IMA need to be sampled, the Kocher maneuver is used to reflect the duodenum medially. The peritoneum lateral to the convexity of the C-curve of the duodenum is incised and the second portion of the duodenum is then dissected off of the IVC. For further exposure, the peritoneal incision along the line of Toldt may need to be extended cephalad to mobilize completely the hepatic flexure of the colon (Fig. 9.15). The right ovarian artery and vein are identified and divided. The right-sided paraaortic lymph nodes are then able

FIGURE 9.14. With the ureter and ovarian vessels identified, the dissection begins at the right common iliac artery and proceeds cephalad up to the third portion of the duodenum.

FIGURE 9.15. The Kocher maneuver can be used to gain access to the lymph nodes above the IMA. The peritoneum lateral to the convexity of the C-curve of the duodenum is incised and the second portion of the duodenum is then dissected off of the IVC. The common bile duct and pancreatic duct enter the second portion of the duodenum posteromedially. For further exposure, the incision along the line of Toldt can be extended cephalad to mobilize completely the hepatic flexure of the colon.

to be dissected off of the IVC and right aorta up to the level of the renal vessels.

The lateral approach to the left paraaortic lymph nodes is accomplished in a similar fashion by incising along the line of Toldt and mobilization of the left colon medially (Fig. 9.16).

FIGURE 9.16. The lateral approach to the left paraaortic nodes is accomplished by retracting the descending colon medially and incising along the line of Toldt.

FIGURE 9.17. Using sharp and blunt dissection, the left colon can be mobilized medially, exposing the left ureter, ovarian vessels, and aorta.

Again, the ureter and ovarian vessels are identified on the undersurface of the reflected peritoneum, and they may be left attached or mobilized laterally for better exposure (Fig. 9.17). After further mobilization of the left colon and identification of the aorta and the IMA, the left-sided nodes are removed in a caudad-to-cephalad direction (Fig. 9.18). Dissection of the nodes

FIGURE 9.18. Dissection begins at the left common iliac artery and proceeds cephalad using hemostatic clips. Care should be taken to avoid injury to the inferior mesenteric artery that arises approximately 3 to 4 cm above the aortic bifurcation.

FIGURE 9.19. The “sunrise” incision. In the center, the incision is approximately 6 cm above the umbilicus. The incision is carried laterally in a downward fashion to the level of the iliac crests.

above the IMA requires mobilization of the splenic flexure of the colon, division of the left ovarian artery and vein, and occasionally ligation of the inferior mesenteric artery.

Extraperitoneal Approach to the Paraaortic Nodes

The extraperitoneal approach to the paraaortic lymph nodes by means of a supraumbilical transverse sunrise incision was initially described by Gallup et al. (11). The skin incision is made 6 cm above the umbilicus in the midline and is carried laterally and caudad to the level of the iliac crests bilaterally (Fig. 9.19) (2).

The fascia is incised transversely. The rectus muscles are dissected off of the anterior-lying fascia cephalad and caudad. The right rectus muscle is transected. The right transversus muscle is then identified and transected caudally and laterally. The hand of the operator is inserted deep into the incision until the right psoas muscle and external iliac vessels are palpated. The peritoneum is then bluntly dissected from caudad and lateral to cephalad and medial, separating it from the underlying common iliac vessels until the great vessels are exposed (Fig. 9.20) (2). If the peritoneum is inadvertently entered, it must be closed immediately.

After identification of the right ureter and ovarian vessels, the right paraaortic nodes can be removed. In thin patients, the left paraaortic nodes may be able to be removed through a right abdominal approach. However, if exposure is difficult, the left rectus and transversus muscles can be transected and the peritoneum mobilized medially in a similar fashion to gain access to the left paraaortic nodes.

Radical Hysterectomy

Although radical hysterectomy is a traditional procedure in gynecologic oncology, with a history of almost 100 years, its performance is still poorly standardized. Different terminology and

FIGURE 9.20. With the rectus and transversus muscles transected, the operator's hand is inserted caudad until the psoas muscle and external iliac vessels are palpated. The peritoneum is then bluntly dissected from caudad and lateral to cephalad and medial, separating it from the underlying common iliac vessels until the aorta and vena cava are exposed.

classifications are currently used to describe individual types of the procedure. As a consequence, the extent of the parametria resection may vary substantially between institutions and surgeons, even if the same terminology is used.

There are several key principles for the classification of radical hysterectomies. First, the key and sole parameter for differentiation between types of radical hysterectomy should be the extent of parametria resection. The resection or removal of other organs or structures should not determine the type of the procedure, including the size of vagina resection. Second, the extent of resection should be precisely defined for all three parts of the parametria (ventral, lateral, dorsal) and in three planes (sagittal, frontal, and transverse) (Fig. 9.21). Mainly surgical margins in vertical (deep parametrial) dimension determine long-term morbidity due to the localization of vegetative nerves

FIGURE 9.21. Three parts of the parametria. **A.** ventral parametrium; **B.** paravesical space; **C.** lateral parametrium; **D.** ureter; **E.** pararectal fossa; **F.** dorsal parametrium; **G.** sacro-uterine space; **H.** rectum; **I.** cervix.

Table 9.1 Proposed Classification System and Corresponding Historical Types of Radical Hysterectomy

New Classification System	Corresponding Types
A	Extrafascial hysterectomy
B	Modified radical hysterectomy Type II radical hysterectomy
C1	Nerve sparing radical hysterectomy
C2	Type III radical hysterectomy Classical/standard radical hysterectomy
D	Laterally extended parametrectomy

in the caudal part of all 3 parts of the parametria. Third, the extent of the procedure and its classification may be different on each side of the cervix if the tumor growth is asymmetrical. Fourth, although the classification system is usually proposed for radical hysterectomy, it is applicable to the radical trachelectomy and the radical parametrectomy.

Two classification systems are most frequently used in the current literature. The classical one published by Piver, Rutledge, and Smith in 1974 classified radical hysterectomy into five types, but the type II and III procedures, which are the most clinically relevant, are the best described (14). Recently, a new system has been proposed by Querleu and Morrow (15) and later extended into three dimensions (16).

Five types of the procedure (A, B, C1, C2, and D) correspond well to other common historical types of radical hysterectomy (Table 9.1). Several aspects make the new classification system unique: the system a) recognizes the size and type of parametrial resection as crucial and the sole parameter for classification, b) includes new type of nerve sparing procedure, c) uses stable anatomic landmarks for the description of surgical resection margins, and d) identifies surgical landmarks in three planes—frontal, sagittal, and horizontal.

The type B radical hysterectomy corresponds mostly to the type II or modified radical hysterectomy. The aim of the procedure is to remove limited parts of the lateral and dorsal parametria (Figs. 9.22, 9.23, and 9.24). The ureter must be identified in the parametrium, unroofed, dissected from the cervix and displaced laterally. The resection margin is indicated by the ureteral bed. The ureteral artery, branching from the uterine artery at its crossing of the ureter, can serve as a helpful lateral landmark. Dorsally, type B aims at the resection of 1 to 2 cm of the dorsal parametria. Identification of autonomic nerves is not required, as it remains preserved in the parametria deeply below the resection margins.

A major intention of the nerve sparing (C1) radical hysterectomy is to remove corresponding parts of ventral, lateral, and dorsal parametria but, at the same time, preserve major autonomic nerve supply to urinary bladder, upper vagina, and rectum (Figs. 9.22, 9.23, 9.24). Two types of vegetative nerves can be identified and spared: (a) the inferior hypogastric plexus, running in the lateral part of the dorsal parametrium, laterally to the cervix below the ureter at the level of the vaginal fornix and ventrally in the infraureteral part of the ventral parametrium towards the urinary bladder; and (b) the splanchnic nerves localized at the bottom of the lateral pararectal space and in the caudal part of the lateral parametrium below the parametrial veins. Surgical margins for the nerve sparing procedure must be kept above the course of the nerve structures in the ventral, lateral and dorsal parametrium. Dorsally, the nerve sparing procedure requires a dissection of two parts of the dorsal parametrium. The mesoureter (fine structure stretched

FIGURE 9.22. Resection lines for types B, C1, and C2 radical hysterectomy on the lateral parametrium. **A.** paravesical space; **B.** vaginal vein; **C.** internal iliac vein; **D.** uterine vein; **E.** uterine artery; **F.** pararectal fossa.

between the ureter and the sacral bone), containing major branches of the hypogastric plexus, is separated laterally from the uterosacral ligament, which allows for an adequate resection of the latter. On the lateral parametrium, the caudal resection margin is indicated by the vaginal vein, the largest parametrial vein, which guarantees the preservation of splanchnic nerves in the caudal part of the lateral parametrium. Ventrally, the ureter is only partially dissected from the ventral parametrium, allowing for limited resection of the proximal supraureteral part of the ventral parametrium.

The radicality of the C2 procedure, which corresponds to the type III radical hysterectomy, is different from the nerve sparing procedure, aiming at removal of the majority of all three parametrial parts (Figs. 9.22, 9.23, and 9.24). The C2 procedure requires complete dissection of the ureter from the lateral and ventral parametria and deeper dissection of the rectum from the dorsal parametria. The resection line on the dorsal parametria is deep below the former rectal attachment, causing unavoidable damage of the hypogastric plexus, so the dissection of the nerve from the uterosacral ligament is not required. The lateral

FIGURE 9.24. Resection lines for types B, C1, and C2 radical hysterectomy on the dorsal parametrium after dissection of the mesoureter from the sacrouterine ligament. **A.** ureter; **B.** mesoureter; **C.** space between the sacrouterine ligament and mesoureter; **D.** branches of the hypogastric plexus (white strips); **E.** sacrouterine ligament; **F.** cervix.

parametrium is completely separated from the pelvic side wall until the sacral bone is reached. On the ventral parametrium the ventral resection margin is formed by the urinary bladder. As a consequence, major branches of vegetative nerves are sacrificed during the C2 type procedure.

Ovarian Cancer Debulking

The goal of ovarian cancer debulking or cytoreduction is to remove all or as close as possible to all grossly visible and palpable tumor (17). The surgeon operating on patients with advanced ovarian cancer should be familiar with the techniques used to clear tumor from the pelvis and the upper abdomen.

Removal of Pelvic Disease

Ovarian malignancy often presents with large pelvic masses filling the pelvis. An initial incision over the lateral pelvic sidewall just anterior to the external iliac artery will allow adequate visualization of the ureter and the ovarian vessels (Fig. 9.25). The paracolic gutters can be incised cephalad along the avascular line of Toldt for more adequate exposure of the retroperitoneal space. To avoid further troublesome hemorrhage with large adnexal masses, if a hysterectomy is part of the planned procedure, the uterine vessels can be separately isolated and divided similar to a modified radical hysterectomy. When the anatomy is distorted by peritoneal implants, the ureters may need to be followed down to the tunnel and retracted laterally prior to removal of the uterus.

In cases where the pouch of Douglas is deeply infiltrated by disease, especially if it involves the rectosigmoid colon, a reverse hysterectomy can facilitate complete removal of the infiltrated peritoneum and help identify the rectovaginal plane sparing a larger part of the rectum for further anastomosis. The term modified posterior exenteration is commonly used for the above procedure, as it aims at en bloc removal of the uterus, adnexa, infiltrated peritoneum, and the rectum. The procedure starts with the incision of the vesical peritoneal plica and dissection of the urinary bladder down to the level of the vaginal fornix. In cases of carcinomatosis on the peritoneal plica, a ventral peritonectomy—complete dissection of the infiltrated peritoneum

FIGURE 9.23. Resection lines for types B, C1, and C2 radical hysterectomy on the ventral parametrium. **A.** paravesical space; **B.** umbilical ligament; **C.** ureter.

FIGURE 9.25. The ovarian vessels are skeletonized and divided at the pelvic brim. Early control of these vessels will help reduce blood loss during the later dissection. The ureter can be mobilized off the medial leaf of the broad ligament and retracted laterally on a Penrose drain or vessel loop.

from the urinary bladder—is part of the procedure. The retroperitoneum is opened laterally above the large vessels, both round ligaments are cut, the ureters are identified, and then the ovarian vessels are ligated and cut. The peritoneum is dissected from both ureters and the sigmoid colon is divided above the level of tumor infiltration. In some cases the infiltrated peritoneum is densely adherent to the ureter in the lateral parametria, so the complete removal of the tumor requires unroofing of the ureter in its parametrial part, and its dissection from the cervix and infiltrated parametria, identical to that performed during a radical hysterectomy. Once the uterine vessels are ligated bilaterally, the rectovaginal space between the vagina and the infiltrated pouch of Douglas is opened, the uterosacral ligaments are cut, and a reverse hysterectomy is completed by the incision of the vagina at the level of the vaginal fornix (Fig. 9.26). The vagina is sutured. At this stage, the specimen is fixed in the pelvis only by the rectum and pararectal ligaments. It allows for the retraction of the specimen cephalad, and in most cases partial cranial dissection of the infiltrated pouch of Douglas from the rectum, aiming at preservation of a larger part of the rectum for further anastomosis. After cutting pararectal ligaments, the exenterative part of the procedure is completed by the incision of the rectum below the level of tumor involvement. Low rectal anastomosis in this setting is generally performed and, in well-trained hands, is associated with a low rate of complications (18,19).

Upper Abdominal Disease

A recent meta-analysis by Bristow et al. demonstrated that expert centers with primary optimal cytoreduction rates of 75% or greater provided their patients with a 50% improvement in overall survival when compared to less experienced centers with primary optimal cytoreduction rates of 25% or less (20). A subsequent study by Chi et al. illustrated that in order to achieve primary optimal cytoreduction rates of 75% or more in

FIGURE 9.26. The posterior vaginal wall is grasped and retracted cephalad. The uterus can now be sharply dissected off of the rectosigmoid.

advanced-stage ovarian cancer patients, the surgeon's armamentarium should include the ability to remove disease involving upper abdominal structures such as the liver, diaphragm, spleen, and pancreas (5).

Adequate exposure is the most important factor in determining whether resection of diaphragm disease can be performed safely (7). Once an exploratory laparotomy has been performed and the presence of bulky diaphragm disease confirmed on one or both hemidiaphragms, the midline incision is extended to the xiphoid process. For maximum exposure, the incision can be extended to the sternum to the right of the xiphoid, or in some cases the xiphoid can be divided or removed. The procedure can almost always be performed through this midline incision, and although extending a subcostal incision 2 to 3 cm below the costal margin has been described, we have not generally found this to be necessary.

The extent of liver mobilization required depends on the distribution of tumor involving the hemidiaphragm. Large volume disease is common on the right side, and a greater proportion of the right hemidiaphragm is obscured by the liver. A right-sided liver mobilization will be described primarily. Tumor involvement on the left diaphragm is more easily resected without fully mobilizing the liver, although in certain cases splenectomy may be necessary to clear the metastatic deposits on the left diaphragm.

The infrahepatic edge of the falciform ligament containing the ligamentum teres is grasped between two Kelly clamps, and is divided and ligated. The suture on the lower edge is left long to aid with downward traction of the liver and remaining falciform ligament. The falciform ligament should be transected all the way to the coronary ligament. This can be used for traction of the liver. The coronary ligament is incised from the falciform to the right triangular ligament. Care must be taken in the area of the hepatic notch. The hepatic notch contains the right hepatic vein as it enters the inferior vena cava and is found lateral to the

union of the falciform and coronary ligaments. If further mobilization of the liver is necessary, the lateral attachments may be incised and the liver bluntly lifted off Gerota's fascia of the right kidney and diaphragm.

The extent of diaphragm peritonectomy is determined by the distribution of the tumor implants, and the method can be modified accordingly. When a full right diaphragm peritonectomy is performed, the peritoneum on the anterior edge of the diaphragm is incised along the costal margin using either cautery or Metzenbaum scissors. This anterior free edge is grasped with several Allis or Mixer clamps, which are then retracted inferiorly to visualize the line of attachment between the diaphragm and its overlying peritoneum. The plane between is developed with a combination of blunt and sharp dissection as determined by the patient's tissue laxity and/or peritoneal adherence. This may not be possible if the tumor has extended through the peritoneum and diaphragm.

If tumor implants are securely fixed to the diaphragm muscle and/or are suspicious for full thickness diaphragm involvement, diaphragm resection should be considered. The technique for diaphragm resection depends largely on the size of the lesion to be resected. Small penetrating lesions can be resected using the EndoGIA stapler alone without entering the pleural cavity. The lesion is grasped with a long Allis clamp, the diaphragm tented downward away from the lung, and the EndoGIA used to staple and divide the tented diaphragm and invasive lesion. Larger lesions require entry into the pleural space and this is generally performed sharply with a Metzenbaum scissors to avoid an inadvertent cautery burn to the lung. Once entered and the lung visualized/retracted, cautery can be used to circumscribe the lesion and resect it en bloc with the peritoneal, muscular, and pleural layers. The defect can almost always be closed primarily with limited tension, using interrupted horizontal mattress or figure-of-eight permanent sutures. Larger defects that cannot be closed primarily without significant tension should be closed with a permanent mesh secured to the peritoneal diaphragm surface with interrupted permanent sutures (21). The majority of patients undergoing diaphragm resection can have their pleural cavity closed and the air from the thorax evacuated using the red Robinson catheter. A purse-string suture is placed widely around the hole and a #14 French red Robinson catheter is passed through the hole into the pleural cavity. The anesthesiologist is asked to give the patient a maximal inspiration, suction may be applied to the catheter, and the catheter is pulled as the purse-string suture is tied down. For patients undergoing more extensive resections or with other reasons to benefit from prolonged pleural drainage, such as pleurodesis, a chest tube can be placed in the operating room and removed postoperatively as required.

To remove tumor from the left upper quadrant, occasionally a splenectomy with or without distal pancreatectomy is required. Usually, the initial step is to enter the lesser sac to evaluate the posterior aspect of the stomach and pancreas. The gastrosplenic ligament and then the short gastrics are carefully divided. The spleen is mobilized medially and out of the left upper quadrant by dividing the splenophrenic and splenocolic ligaments and the other attachments to the adrenal gland and Gerota's fascia of the left kidney. The spleen can now be elevated out of the splenic bed and into the incision. The splenic hilum is now grasped between the fingers. Palpation of the pancreas is attempted. Identification of the pancreas may be facilitated by viewing the hilum posteriorly. The anterior splenorenal ligament is entered sharply. The splenic artery and vein can then be identified. These vessels should be ligated and divided separately. The splenic vessels may also be ligated prior to elevating the spleen in cases where lateral mobilization is not possible secondary to tumor and/or dense adhesions. A linear stapler may be placed across the tail of the pancreas if necessary to remove tumor involving the distal pancreas and/or splenic hilum. Reinforcement of this staple

line with 3-0 delayed absorbable suture, either continuously or interrupted, is optional.

Continent Urinary Diversion

Over the past two decades, interest in performing continent urinary diversions for patients with gynecologic malignancies has emerged. Most gynecologic oncologists will use a modification of the Indiana (22) or Miami (23) pouch. Poor candidates for continent urinary diversion include those with crippling arthritis or those psychologically unable to tolerate frequent self-catheterization of the pouch.

A modification of these pouches is shown (2). The colon is transected just proximal to the hepatic flexure (Fig. 9.27). The colon is then detubularized by a longitudinal incision along the tinea. The continent mechanism is created by two maneuvers. First, the terminal ileal segment is tapered down over a #14 French Foley catheter by using a gastrointestinal anastomosis (GIA) stapling device along the antimesenteric border of the ileum. The second maneuver is to plicate the ileocecal valve by placing concentric purse-string sutures of 0 silk or polypropylene around it. The ureters are then implanted under direct vision (Fig. 9.28) (2). After closing the pouch, the ileal stoma can be brought out in several areas of the abdominal wall (Fig. 9.29) (2). Some use the umbilicus as the exit site. The ureteral stents can exit the abdomen via the ileal stoma or through separate incisions in the pouch and abdominal wall. The use of a Penrose drain and a cecostomy tube for irrigation to remove mucus is optional.

Abdominal Closure

With the advent of more recently published closure methods and newer suture materials, the vertical, allegedly stronger paramedian incision is unnecessary. A midline incision is preferable in modern-day gynecologic oncology. It is the least hemorrhagic of all incisions, and rapid entry is feasible. Exposure is excellent, and minimal nerve damage occurs.

In the past, many surgeons have advocated the relatively time-consuming Smead-Jones closure (24). However, in the 1980s it was noted that midline incisions could be safely closed with a running, mass closure. In 1989, Gallup et al. (25) reported on 210 patients, most of whom were at high risk for evisceration. In those who had midline incisions closed with a running, mass closure using #2 monofilament polypropylene suture, no eviscerations occurred. Since that publication, several series have published excellent results using monofilament absorbable or monofilament permanent sutures in a running, mass closure method (26–28). Fascial closure should be performed with a suture length to wound length ratio of at least 4:1 (29). In addition, a randomized trial in nongynecologic cancer patients demonstrated that placement of fascial sutures 5 to 8 mm from the fascial edge (as compared to the traditional >10 mm from the fascial edge) results in fewer surgical site infections and fewer ventral hernias (28).

SURGICAL MANAGEMENT OF GYNECOLOGIC CANCER

The gynecologic oncologist must be able to evaluate the woman with a genital tract malignancy, direct her management, perform the necessary surgical procedures, and supervise her postoperative care and surveillance. A patient who is managed by a surgeon who is not a gynecologic oncologist may receive an operative procedure that is inappropriate or inadequate. Over 20 years ago, McGowan et al. (30) reviewed the intraoperative evaluation of

FIGURE 9.27. The anatomic location and vascularity of the right colon segment utilized for formation of the continent urinary pouch. Illustrated are the anatomic sites of division for creation of the continent pouch. The ascending colon is divided distal to the right colic artery. The terminal ileum is divided approximately 12 cm from the ileocecal valve. The resection can be accomplished with the use of surgical staplers or by intestinal clamps. If the appendix is present, it should be removed. The ileocecal segment has a rich blood supply derived from the right colic artery and the ileocolic artery. If one is performing the Miami pouch type of urinary diversion, the transverse colon would be divided distal to the middle colic artery.

291 women with primary ovarian cancer. Ninety-seven percent of the patients who underwent surgery by a gynecologic oncologist received complete staging operations, but only 52% and 35% had adequate operations performed by an obstetrician-gynecologist or a general surgeon, respectively.

Two more recent British studies retrospectively analyzed the outcomes of over 1,800 patients with ovarian cancer (31,32). Both studies found on multivariate analysis that patients' survival was adversely affected when their initial operation was performed by a general surgeon, as opposed to a gynecologic surgeon. These results are similar to those obtained by Nguyen et al. in an American national survey of ovarian carcinoma (33). Eisenkop et al. analyzed the outcomes of 263 patients with stages IIIC and IV ovarian carcinoma (34). When the primary surgery was performed by gynecologic oncologists, as compared to general obstetricians-gynecologists and general surgeons, the rate of optimal cytoreduction was significantly higher, the operative mortality substantially lower, and the median survival significantly longer.

Accordingly, other countries have attempted to centralize the care of patients with ovarian cancer so that they are primarily operated on by gynecologic oncologists (35,36). However, patterns of care studies in the United States have demonstrated that a significant percentage of women with ovarian cancer are not receiving their primary treatment from gynecologic oncologists (37,38). Consequently, in this country, many women with ovarian cancer are still not receiving the recommended comprehensive primary surgery (39,40).

In the four decades since the establishment of gynecologic oncology as a subspecialty, cancer therapy has become increasingly sophisticated and complex, and it is difficult for any one physician to master all the skills necessary for treating gynecologic malignancies. More often, we must use multimodal therapy and participate in multidisciplinary care. There are many medical and radiation oncologists who have specialized in gynecologic cancer, and they are integral members of the multidisciplinary team. The Gynecologic Oncology Group (GOG), with its emphasis on multidisciplinary research, has demonstrated the effectiveness of such an approach.

Another important factor in providing optimal patient care is the environment in which gynecologic oncology is practiced. The facilities used by the gynecologic oncologist should offer state-of-the-art radiation therapy and chemotherapy. Patients should receive care tailored to the type and extent of their disease and not have their treatment determined by the limitations of the available facilities. Mortality rates for complex oncologic procedures, such as pelvic exenteration, have been demonstrated to be significantly lower in hospitals where the procedures are performed with a relatively high volume as compared to those in which the procedures are performed infrequently (41). The recent meta-analysis performed by Bristow et al. evaluated 81 studies involving 6,885 patients with advanced ovarian cancer (20). This study demonstrated a 50% increase in median survival if patients' primary surgery was performed at an "expert" center compared to less experienced centers.

FIGURE 9.28. A, B: Prior to beginning the continent diversion, the ureters have been transected (usually at the pelvic brim) and mobilized so that they are able to be brought to the area where the continent pouch will be located without tension. If necessary, the left ureter can be brought through or under the mesentery of the colon to facilitate its placement into the urinary pouch. An appropriate site is selected on what will be the posterior wall of the pouch, and a long thin clamp is used to perforate the colon and pull the ureter through. An approximately 1-cm segment of ureter is brought into the pouch. For ease of ureterointestinal anastomosis, the ureter should be secured posteriorly to the pouch by suturing the adventitial tissue of the ureter to the seromuscular layers of the pouch with 3 or 4 permanent 3-0 sutures. The ureter is spatulated to increase the lumen diameter. The ureter is sutured directly to the colon and is not tunneled. We use 4-0 polyglycolic suture. This is a full-thickness approximation of the colon and ureter. Once both ureters have been sutured into the pouch, 2 #8 French ureterointestinal stents or long pediatric feeding tubes are placed retrograde into the renal pelvis. If a feeding tube is used, it should be sutured to the ureter with 4-0 chromic to ensure against displacement due to ureteral peristalsis. Note the 3 concentric sutures at the ileocecal valve.

Early Diagnosis and Prevention

There is a role for early diagnosis and prevention in virtually all female genital cancers. The management of a patient with an abnormal Papanicolaou (Pap) smear allows the gynecologic oncologist to use limited surgery to prevent the development of an invasive malignancy of the cervix or vagina. Guided by colposcopy, the surgeon can employ traditional surgical excision, laser surgery, cryotherapy, or a loop electrosurgical excision procedure (LEEP) to preserve function and prevent cancer. Preinvasive lesions of the vulva can be diagnosed and managed by laser or local excision, thereby potentially avoiding progression to invasive disease and its associated extensive surgical therapy.

The proper management of endometrial hyperplasia can prevent the subsequent development of endometrial cancer. Optimal management requires individualization of treatment. Complex hyperplasia without atypia in a premenopausal patient indicates

the need for medical therapy with progesterone, but a similar problem in a postmenopausal patient may indicate the need for a hysterectomy. Atypia in either case requires consideration of hysterectomy to prevent the development of endometrial cancer. It is essential that the gynecologic oncologist recognize the significance of these cancer precursors.

No diagnostic test or early symptoms reliably herald the onset of ovarian or tubal cancer, and no preinvasive lesion has been identified. The only method of prevention for these cancers is surgical removal of the tubes or ovaries before cancer develops. Although it occurs very rarely, some women may have an identified lifetime risk of as high as a 40% of developing ovarian cancer. These are women who have a family history of ovarian cancer, who have a family history of breast and ovarian cancer, or who are members of hereditary nonpolyposis colorectal cancer (HNPCC) families. These cancer-prone families are described elsewhere in this book. These syndromes are seen infrequently,

FIGURE 9.29. A, B: The site for the ileal stoma is selected on the anterior abdominal wall and then incised through all abdominal tissue layers. The stoma is created for catheterization and the #14 French catheter should exit the pouch through this stoma. It is critical that the ileal segment be at a 90° angle with the abdominal wall so that catheterization is a “straight shot.” The pouch may be sutured to the abdominal wall to accomplish this. All stents and drainage tubes are brought out through the anterior abdominal wall and secured. The pouch may also be anchored posteriorly (i.e., to the sacrum). Source: Reprinted with permission from Gallup DG, Talleo OE. *Surgical Atlas of Gynecologic Oncology*. Philadelphia, PA: W.B. Saunders Co.; 1994:193.

and certain criteria must be fulfilled before the diagnosis can be made. For women who fall into one of these high-risk categories, surgical removal of the tubes and ovaries (and the uterus in HNPCC) should be considered after childbearing is complete (42,43). Before that time, close monitoring is essential.

Diagnosis and Staging

The diagnosis of any gynecologic cancer requires a surgical biopsy. The manner in which the histologic diagnosis is obtained varies with the disease and the clinical situation. A punch biopsy or an instrument biopsy may be sufficient for the diagnosis of an invasive cancer of the vulva, vagina, or cervix, but an excisional biopsy is necessary for the diagnosis of microinvasive or preinvasive cancer. A fine-needle aspiration biopsy for cytologic analysis

Table 9.2 FIGO Staging of Gynecologic Cancers

Site	Staging
Vulva	Surgical and pathologic staging
Vagina	Clinical staging
Cervix	Clinical staging
Corpus (endometrium)	Surgical and pathologic staging
Corpus (sarcoma)	Surgical and pathologic staging
Fallopian tube	Surgical and pathologic staging
Ovary	Surgical and pathologic staging
Gestational trophoblastic disease	FIGO staging (clinical)
	WHO classification (risk-oriented)

FIGO, International Federation of Gynecology and Obstetrics; NIH, National Institutes of Health; WHO, World Health Organization.

may be adequate for establishing the extent of spread of a cancer, but not for providing histologic cell type and grade for the primary diagnosis. The histologic diagnosis of ovarian or fallopian tube carcinoma requires surgical exploration.

The current International Federation of Gynecology and Obstetrics (FIGO) staging system of gynecologic cancers requires surgical staging for vulvar, endometrial, and ovarian cancer. Cervical cancer remains a clinically staged disease, although many centers use surgical staging (by laparotomy or laparoscopy) for treatment planning. Table 9.2 lists the current methods of staging for the various gynecologic malignancies.

The initial surgical procedure in a patient with known or suspected gynecologic cancer should be performed by a trained gynecologic oncologist because the accuracy of diagnosis and staging significantly influences subsequent therapy. As stated earlier, numerous studies have demonstrated that ovarian cancer staging operations performed by general obstetricians-gynecologists or general surgeons are inadequate much more frequently than if the operation is performed by a gynecologic oncologist. Young et al. (44) reported excellent survival in patients with early ovarian cancer, but stressed that these data were applicable only to patients with adequate surgical staging.

In addition to the anatomic site and stage of disease, the plan of therapy for most gynecologic malignancies is also influenced by the histologic cell type and histologic grade (differentiation) of the cancer. The cooperation of the surgeon, pathologist, and cytologist cannot be overemphasized in the diagnosis and staging of cancer. It is the surgeon’s responsibility to provide the pathologist or cytologist with a complete clinical history and an indication of what he or she hopes to learn from the anatomic specimen. Without this communication, the pathologist and cytologist will be unable to provide the information needed to direct the clinical care of the patient. Both the pathologist and the cytologist must be sure that the surgeon is aware of any special handling that is necessary for a particular specimen. There is no excuse for misinterpretation of a tissue or cytologic specimen because of a failure in communication.

Surgery as Primary Therapy

Surgery is usually the treatment method of choice for preinvasive diseases of the vulva, vagina, and cervix, for which local excision

is both diagnostic and curative. Surgical margins should clear only gross and microscopic disease; removal of large areas of normal tissue is not required. For microinvasive lesions of these organs, wide local excision with a 1- to 2-cm normal tissue margin is appropriate.

Localized disease, such as stage I vulvar cancer, stage I posterior vaginal cancer, and stage IA2/IB1 cervical cancer, are usually managed by radical resection of the primary tumor and regional lymphadenectomy. Some centers utilize sentinel lymph node evaluation instead of complete regional lymphadenectomy. In these surgical procedures, the operations themselves are designed to be curative without adjunctive therapy unless high-risk conditions are identified. As described in the chapter on vulvar cancer, there is a trend toward more conservative therapy for vulvar malignancies. This allows preservation of normal tissues and prevents some of the disfigurement that can be associated with this surgery. Surgery may be curative without adjuvant therapy for other cancers as well, including early-stage endometrial cancer, stage IA ovarian cancer, and early sarcomas of the uterus.

Findings at surgery may indicate the need for additional treatment. This therapy is usually called adjuvant therapy. It is administered because of the potential for occult spread of disease based on a surgical finding (e.g., positive lymph nodes). The use of adjuvant therapy requires that information be available to allow the selection of patients with a high risk of recurrence. These risk groups are defined for each disease site in the appropriate chapters of this book.

Surgery Combined with Other Therapies

In some cancers of the female genital system, surgery is the cornerstone of treatment but is not curative when used alone. Primary cytoreduction of gross disease is vital in advanced ovarian and fallopian tube cancer, but it is of little benefit without adjunctive therapy. Chemotherapy after surgery is a vital and necessary part of the treatment regimen for these cancers. For patients with clinical stage I or II endometrial cancer who have high-grade cancer or deep myometrial penetration, surgical removal of the uterus is an extremely important part of therapy. However, depending on the histopathologic findings of the surgical specimens, additional regional radiotherapy and/or chemotherapy may be indicated. It is the responsibility of the gynecologic oncologist to coordinate surgical therapy with chemotherapy and/or radiation therapy to ensure that the patient receives optimal care.

Surgery as Salvage Therapy

Occasionally, surgical resection can be curative in patients in whom other therapies have been unsuccessful. These surgical procedures are almost always extensive and produce some limitation of function. After the failure of other therapies, radical surgery may be the patient's last chance of survival. The classic examples of this situation are vulvar, vaginal, cervical, or uterine cancers that have not been cured by primary surgery and irradiation or irradiation alone. In such cases, pelvic exenteration with removal of virtually all pelvic tissues may offer the only possibility for a cure. Five-year survival rates of 23% to 61% have been reported after pelvic exenteration (45–47).

The possibility of cure with pelvic exenteration is not without cost. The loss of the bladder and the rectum often requires permanent stomas, and sexual function is impaired or lost in many patients. For some patients, reconstructive techniques can prevent the need for stomas and may also restore sexual function. These procedures are described in detail in other chapters in this book. During the last three decades, improvements in initial surgery and radiation therapy along with refinements in selection criteria have made operations like pelvic exenteration infrequent (48). Today, most patients experience distant failure rather than regional failure, and they are therefore not candidates for attempts at curative pelvic exenteration.

Surgery as salvage therapy may also play an important role in the management of ovarian, fallopian tube, and some endometrial cancers. For patients who have not been cured by initial therapy and chemotherapy, second attempts at cytoreduction may be beneficial, provided that reasonable salvage therapy is available (49–51).

Surgery for Metastatic Disease

In selected cases, distant metastases from gynecologic tumors may be curable by surgical resection, or the resection may produce a prolonged disease-free interval. Fuller et al. (52) reported on 15 patients who underwent pulmonary resection of distant metastases from a variety of gynecologic malignancies. They reported a 5-year survival rate of 36% and a 10-year survival rate of 26%. Patients with solitary metastases had a median survival of 64 months, with a median survival of 48 months for those with multiple metastases. Levenback et al. (53) reported their experience with 45 patients who underwent pulmonary resection of metastases from uterine sarcomas. From the date of the pulmonary resection, the 5-year survival rate was 41%, with a 10-year survival rate of 35%. The investigators found a statistically improved chance of survival for patients who developed pulmonary metastases 1 year or longer from their original therapy and for those with unilateral metastases. There was no statistical difference in survival based on the number of nodules (in one lung), the size of the lesion, the age of the patient, or the use of postresection adjunctive therapy. However, the small number of patients in this study precluded adequate evaluation of these factors.

Resection of intra-abdominal or pelvic disease may offer palliation by removal of tumor bulk, or may allow chemotherapy or irradiation a greater chance of eradicating disease. Resection of tumors that have a poor blood supply often leaves behind smaller tumors with a better blood supply that are more amenable to treatment with chemotherapy or irradiation. Resection of bulk disease also increases the number of residual tumor cells that enter the active cell cycle, in which they may be more responsive to these adjunctive therapies. The availability of new techniques for intraoperative electron beam irradiation or intraoperative brachytherapy may result in more utility for resection of distant and regional metastatic disease.

There is increasing evidence that salvage therapy in ovarian and fallopian tube cancers is likely to be effective only in patients with minimal residual disease. Secondary cytoreduction or resection of regional and distant metastases may play an important role in the treatment of these patients. Recent reports have demonstrated promising results with surgical resection of isolated metastases to the parenchyma of the liver and spleen (54,55).

Surgical Procedures for Specialized Care

Surgical placement of indwelling intravenous access systems allows patients to receive chemotherapy and nutritional supplements and to have necessary blood samples drawn with relative ease and comfort. Placement of these devices, usually semipermanent subcutaneous systems, is safe, contributes to the patient's well-being, and allows for more effective therapy.

The use of intracavitary therapy requires the temporary or semipermanent placement of chest tubes or intraperitoneal access devices. Results of many studies confirm that peritoneal access or vascular access devices placed totally beneath the skin have a low infection rate and a low rate of malfunction (56,57). Implanted arterial infusion devices are being evaluated in research studies to allow direct infusion of therapeutic agents into a tumor mass by means of the arterial system. This therapy often requires intra-abdominal surgery to place the device into the appropriate portion of the vascular system.

Surgery for Reconstruction

Reconstructive surgery may be performed at the time of resection of the cancer, as a delayed procedure, or as required therapy to correct a complication of treatment. Vulvar reconstruction is usually done at the time of initial resection and may involve the use of free skin grafts, rotational flaps of adjacent skin and fat tissue, or myocutaneous grafts from the thigh, buttocks, or anterior abdominal wall. Vaginal reconstruction may also be performed, usually as a planned, delayed phase of reconstruction. Vaginal reconstruction requires free skin grafts or myocutaneous flaps, depending on the size of the defect and whether or not there has been previous irradiation of the vaginal bed. The techniques of vulvar and vaginal reconstruction are explained in detail in Chapters 19 and 20.

Reconstruction as therapy for complications of treatment may be required for the closure of defects from improper wound healing, radiation necrosis, or tissue loss after extravasation of chemotherapeutic agents. Although free skin grafts may be used to reconstruct surgical wound disruption or tissue loss due to chemotherapy extravasation, radiation necrosis usually requires the use of myocutaneous flaps because of a lack of adequate blood supply in the area of the injury.

Surgery for Palliation

Surgery for palliation may involve resection of tumor to relieve symptoms, or it may involve diversion or bypass of portions of the gastrointestinal or urinary tract to prolong life and provide comfort. Surgical procedures may also be used to provide pain relief by interrupting sensory nerve transmissions. Surgical removal of tumor bulk to provide palliation has been discouraged by many authorities. They point out that without effective adjunctive therapy, tumor regrowth occurs quickly and the surgical procedure proves to be futile. Although this may be true in most cases, the gynecologic oncologist should not uniformly dismiss the concept of surgical palliation. A surgical procedure to provide relief of symptoms is usually considered a failure if the tumor regrows in 6 to 12 months. However, palliative administration of a chemotherapeutic agent for 6 to 12 months is considered to be successful if there is minor tumor shrinkage or stabilization of disease despite the side effects of the chemotherapy. As a surgeon, the gynecologic oncologist must remember that a surgical procedure with limited risk and a reasonable recovery period may provide as much relief as 6 to 12 months of palliative chemotherapy or a course of palliative irradiation. The difficult decision about when to employ surgical palliation requires astute surgical judgment and a realistic assessment of the patient's condition and wishes.

Palliative surgery is more frequently used to relieve specific dysfunctions, such as obstruction of the urinary or intestinal tract. Relief of urinary tract obstruction may be accomplished by ureteroneocystostomy or by urinary conduit, depending on the location of the obstruction and the location or extent of disease. A urinary conduit can provide immediate and permanent relief to the patient who has a ureterovaginal, vesicovaginal, or urethrovaginal fistula. It may also provide relief of urinary obstruction, which will prolong life and allow for the administration of additional chemotherapy or irradiation. The judgment of the surgeon and the desires of the patient become essential factors in this decision process. For the patient who is miserable because of constant urinary leakage or who may benefit from additional therapy, the decision to perform a urinary diversion is quite simple. If diversion is done to prolong life, however, the decision must be weighed carefully. For a patient who has a limited life expectancy or is in uncontrollable pain, performing a urinary diversion may do more harm than good.

The gynecologic oncologist must also consider the relative benefits of nonsurgical urinary diversion, such as placement of a ureteral stent or a percutaneous nephrostomy. For many

patients, percutaneous nephrostomy is a better choice than surgical intervention. This is particularly true if the aim is to employ adjunctive chemotherapy or irradiation, or if a surgical procedure is not feasible because of medical conditions or other surgical considerations. Unfortunately, a percutaneous nephrostomy cannot help the patient with a fistula because the nephrostomy will not totally divert the urine.

Placement of a ureteral stent, by cystoscopy or antegrade through a percutaneous nephrostomy, is usually better and safer than urinary diversion for the relief of obstruction. Current technology allows the placement of stents that can be left in place for months and can be changed easily over a guide wire by means of the cystoscope.

Intestinal obstruction threatens the patient's quality of life, and the decision of whether to perform an intestinal diversion is usually easy. Deciding whether the operation is feasible can be more difficult. For the patient with localized disease, a diverting colostomy or an intestinal bypass is usually possible and is not very difficult. For the patient with intra-abdominal carcinomatosis, the decision is more complex. The surgeon may not be able to determine the extent of intestinal involvement preoperatively and may have difficulty deciding whether the surgical procedure will benefit the patient.

Pothuri et al. (58) evaluated 68 palliative operations performed on 64 patients with recurrent ovarian cancer and intestinal obstruction. In 84% of cases, it was possible to perform a corrective surgical procedure, whereas no corrective surgical procedure was possible for the remaining 16%. Of the 57 patients for whom corrective surgery was possible, 71% were successfully palliated ("successful palliation" is defined as the ability to tolerate a regular or low-residue diet at least 60 days postoperatively). If surgery resulted in successful palliation, median survival was 11.6 months compared to 3.9 months for all other patients.

THE FUTURE OF GYNECOLOGIC ONCOLOGY

As of 2012, the subspecialty of gynecologic oncology is over 35 years old. From a cadre of forward-thinking individuals with a variety of training backgrounds, a cohesive subspecialty has developed with consistent standards of training, a system of certification, and recognition in the medical community. None of this has come easily, and we owe a great deal to that first generation of gynecologic oncologists.

Several current issues are affecting the future role of gynecologic oncology within the medical community. Our relationship with our parent specialty of obstetrics and gynecology is being reexamined, as are our ties with general surgery and urology, specialties with which we often seem even more closely allied. As technologic advances occur, we are becoming more integrated with the specialties of medical oncology and radiation oncology. Although we remain primarily surgeons, and surgery remains our principal mode of therapy, it is critical to emphasize the integrated multidisciplinary management of the patient with gynecologic cancer.

The benefits of multidisciplinary care were recently highlighted in a clinical announcement by the National Cancer Institute (NCI) concerning concurrent chemoradiation for cervical cancer (59). In each of five randomized phase 3 trials of women with various stages of cervical cancer, the addition of chemotherapy to radiotherapy was found to provide a significant survival benefit (13,60–63). The risk of death from cervical cancer was decreased by 30% to 50% with the multimodality approach.

Changes in Surgical Therapy

If the past decade is any indication of the future, significant changes in the technology of surgery can be expected to occur as we proceed

through the new millennium. New materials, new surgical instruments, and new devices will be invented, and many of these will make surgical treatment better. Laparoscopic surgery has made a significant impact on our specialty, as well as on the other surgical specialties. With robotic surgery, the complexity of cases that can be successfully performed with minimally invasive surgery appears to have increased, and standard gynecologic oncologic staging procedures appear to be very amenable to the robotic platform.

Innovative methods of supportive care will be developed to advance the technical capabilities that we now possess, such as computerized anesthesia machines and transesophageal ultrasound. Anesthetic agents will become better and safer, and will be joined by a new generation of antibiotics and cardiovascular medications. We will be able to treat the older patient surgically with relative safety, which is especially important because of the increased incidence of cancer in the elderly, and because of the advancing age of our population. Our responsibilities include staying abreast of these advances and judiciously integrating them into our practices.

Changes in the Indications for Surgery

Early diagnosis will change the indications for surgery and the types of procedures that should be done. We will be able to treat more patients with less disfigurement and with greater preservation of function. A larger proportion of patients will present with early disease, allowing surgery to be used more frequently for definitive cure.

Better adjunctive therapies will increase the importance of initial surgical therapy. More patients will benefit from surgical cytoreduction to minimize disease. The availability of effective irradiation, chemotherapeutic, and biologic regimens will make adjuvant therapy feasible in more cases, and it will become more important for us to identify risk groups who are likely to develop recurrent disease after surgery.

Multidisciplinary Therapy and Primary Care

In outlining the extent of surgical training required for the gynecologic oncologist, the founders of this discipline were careful to include adequate training that would enable the gynecologic oncologist to become an accomplished abdominopelvic surgeon. The gynecologic oncologist must be trained to perform the gynecologic, gastrointestinal, and urologic surgery necessary to manage gynecologic cancer and its potential complications. As stated by John L. Lewis Jr. (64), in reference to pelvic exenteration by a team of gynecologists, general surgeons, and urologists, "Even when the

surgery was successful, the postoperative care required committee meetings and its outcome was often less than successful."

These same founders realized that, although training can produce a qualified surgical oncologist, the complete care of the cancer patient requires knowledge of the basic biologic, physical, and pharmacologic principles of radiation therapy and chemotherapy. This does not mean that the gynecologic oncologist must be a radiation oncologist or a medical oncologist, but it does demand that he or she know enough to ensure proper integration of all therapeutic modalities. Throughout the United States, this collaboration in the care of patients with gynecologic cancer has produced multidisciplinary teams of gynecologic oncologists, radiation oncologists, medical oncologists, and pathologists who provide state-of-the-art cancer care. The GOG, a national cooperative research group, has demonstrated how this multidisciplinary approach to gynecologic oncology research can be achieved.

Despite the emphasis on multidisciplinary care, the gynecologic oncologist should maintain active involvement during all aspects of a patient's care. The principle of being the patient's physician until she is either cured or dies of her disease has been an integral part of our subspecialty and must be maintained. The constant involvement of the gynecologic oncologist through all phases of cancer treatment ensures optimal integration of surgery, irradiation, and chemotherapy. The patient receives continuous care and the reassurance of a physician who is involved at each stage of her therapy and follow-up.

CONCLUSION

After three and a half decades, the gynecologic oncologist has emerged as a surgical oncologist for women. The specialist has sufficient familiarity with radiation oncology and medical oncology to ensure the proper integration of all modalities of treatment, and he or she is able to apply surgical skills for primary therapy, secondary therapy, reconstruction, and palliation. The gynecologic oncologist stands in the obstetrics and gynecology community, but has one foot in the community of surgeons.

The emergence of cooperative research groups, particularly the GOG, has allowed a generation of gynecologic oncologists to develop superior clinical research skills. These skills must be continually stressed in the training of young oncologists and as an integral part of the practice of our subspecialty. A growing number of young oncologists are receiving additional training in basic research. This training is vital for the continued development of the subspecialty and for progress toward the prevention and care of gynecologic cancers. Our position in the arena of clinical practice is well established, and we must now establish ourselves equally well as scientists and surgical researchers.

Minimally Invasive Surgery in Gynecologic Cancer

DENIS QUERLEU ■ MARIE PLANTE ■ YUKIO SONODA ■
WALTER GOTLIEB ■ ERIC LEBLANC

Early history of laparoscopic surgery in gynecologic oncology came to an end when the whole range of surgical procedures used in uterine cancer, including pelvic exenteration, was demonstrated to be feasible laparoscopically (1). In a second phase, accumulation of evidence including long-term follow-up of patients managed laparoscopically, results of randomized controlled studies, and meta-analysis has led to unanimous acceptance of the concept of minimal invasive surgery (MIS) in gynecologic cancer. However, notwithstanding the spread of the technique in almost every country in the world, the open approach is still widely used in small institutions with limited caseload, or in academic centers without trained teachers and proctors, which implies that more efforts still have to be made in teaching and in concentrating the management of gynecologic cancer in experienced hands.

In this chapter, the evidence of short- and long-term benefits and safety of the laparoscopic approach, the teaching and learning issues, and the new technical developments will be detailed.

BASICS OF LAPAROSCOPIC SURGERY IN GYNECOLOGIC CANCER

The goal of this section is not to describe the standard technique of laparoscopy; this can be found in general gynecology textbooks. Two issues will be addressed: the risk of bowel and vascular complications related to the laparoscopic approach, and the pitfalls of the laparoscopic approach in cancer patients. Indeed, the potential for inducing severe intraoperative surgical complications and to favor tumor growth and port-site implants is not negligible. The goal of this section is to contribute to the prevention of such complications. Additional tips to make the laparoscopic surgeon's life easier will also be given. An insight on training issues that are critical to the development of laparoscopic surgery versus open and robot-assisted laparoscopic surgery will conclude the section.

Laparoscopic Entry

Laparoscopic surgery was initially performed via CO₂ insufflation to create a pneumoperitoneum through the umbilicus – a place where the layers of the abdominal wall are fused followed by blind insertion in the umbilicus of a 10-mm trocar to accommodate the endoscope. This mode of entry was responsible for bowel and vascular complications, some of them lethal. The use of disposable trocars with retractable blades for direct trocar insertion did not appear to significantly reduce the risk of bowel or vascular injuries. This is of particular concern since the majority

of complications following laparoscopic surgery are related to trocar insertion.

For that reason, the “open” technique in which the fascia and the peritoneum are surgically opened and the trocar inserted under direct visualization is considered by many to be the safest access technique. However, this is likely not to be true in patients with a history of laparotomy, as the majority of bowel adhesions are located on the midline below the umbilicus, at a location where even an “open” technique can result in bowel injury. Bonjer et al. (2) reviewed the literature and compared data between 12,444 open laparoscopic and 489,335 closed laparoscopic cases. Rates of visceral and vascular injury were 0.083% and 0.075%, respectively, after closed laparoscopy, and 0.048% and 0.0%, respectively, after open laparoscopy ($p = 0.002$). Mortality rates were 0.003% for the closed and 0.0% for the open laparoscopy techniques. In another randomized trial of blind versus open laparoscopy for laparoscopic cholecystectomy, the major complication rate was 4% in the blind group and 1.3% in the open group, respectively ($p < 0.05$) (3). However, a large series comparing 8,324 cases of direct laparoscopic entry versus 1,562 cases of open laparoscopy for gynecologic procedures did not show a difference in the rate of major complications. On the opposite, there were more conversions to laparotomy in the open technique group (4). A review on laparoscopic entry concludes that there is no evidence that the open entry technique is superior or inferior to other entry techniques currently available (level II-2C evidence) (5). The visual entry cannula system may represent an advantage over traditional trocars, as it allows a clear optical entry; however, that does not necessarily avoid all visceral or vascular injuries (5).

In patients with prior midline incisions, the use of the Veress needle in the left upper quadrant to first insufflate the abdomen prior to the trocar entry is favored. Once the pneumoperitoneum is established, the location of the first trocar is chosen at a place where the absence of adhesion is evident, as assessed by a 5-mm endoscopy through the left upper quadrant or the use of the “bubble test.” This test consists in exploring the abdominal cavity by puncturing the abdominal wall using a fine needle plugged to a syringe containing 1 to 2 mL of saline. If bubbles are not freely aspirated, there is a suspicion of bowel or omental adhesions. Using multiple punctures if necessary, an area free of adhesions large enough to safely accommodate the endoscope is defined. Although the umbilicus is the traditional site of placement of the first trocar, one must be prepared to use any position in the midline or any site of the abdomen, provided the risk of adhesion is low. It is the policy of the senior author to combine this technique (left upper quadrant insufflation, bubble test) with the use of trocar insertion under direct vision using the Ternamian trocar (6).

The ancillary trocars are placed under laparoscopic vision. Generally, one 10-mm trocar is placed in a suprapubic location. Two 5-mm trocars are then placed on the horizontal line of the

umbilicus, 10 cm lateral to it. This trocar position has many advantages. It allows access to the entire abdomen, from the pelvis to the diaphragm. It provides an adequate angulation between instruments, with a maximum distance between trocars. It provides a direct access, with a virtually 0-degree angle, to the ureteric tunnel at the time of radical hysterectomy. It is more adapted to performance of procedures at the abdominal level such as omentectomy or paraaortic lymph node dissection. Finally, it avoids injuring the iliohypogastric nerves that run oblique in the abdominal wall below the umbilical horizontal line, thus avoiding short and long-term postoperative pain. Any adhesion impairing vision or correct placement of trocar is taken down. When extensive adhesions are encountered, the first 5-mm trocar is placed in an area free of adhesions. Scissors are then introduced and other adhesions are divided to place the other trocars.

Port-Site Metastasis and Risk of Tumor Dissemination

In the early laparoscopic era, there has been concern about the apparent increased rate of port-site metastases following laparoscopic procedures. The first reports concerned borderline tumors of the ovary (7). Isolated case reports of abdominal wall metastasis following laparoscopic surgery for a variety of gynecologic cancers have been reported and reviewed by Ramirez et al. in 2004 (8). The fact that wound recurrences are not uncommon after conventional surgery clearly attenuates the responsibility of laparoscopic surgery in the occurrence of abdominal wall recurrences.

In addition, series from experienced centers have shown that the incidence of port-site growth is low. Zivanovic et al. (9) extended the investigation in the same institution and reported 18 abdominal wall metastases in 1,634 gynecologic cancer patients. Fifteen cases occurred in 767 patients with adnexal/peritoneal malignancy (2%), 2 in 160 cervical cancer patients and 1 in 457 endometrial cancer patients. Seventeen out of 18 of these patients had peritoneal disease, which indicates that abdominal wall metastases are extremely uncommon in the absence of peritoneal disease. In addition, they reported 2 cases in breast cancer patients with intra-abdominal disease, and reported on the outcome of a total of 20 patients. The median survival of patients in whom port-site metastases occurred within 7 months was 12 months, while the median survival of patients who developed port-site metastases after 7 months was 37 months. The conclusion is that the natural history of port-site metastases basically reflects the aggressiveness of the underlying tumor. Martinez et al. (10) reported on 921 patients who underwent laparoscopic staging for cervical cancer and 295 for endometrial cancer. The overall incidence of port-site metastasis after laparoscopy for cervical and endometrial cancer was 0.43% and 0.33%, respectively. Excluding patients with peritoneal carcinomatosis, the rate of port-site recurrence in this series lowered to 0.16%. The rate of isolated port-site metastases was 0%.

In contrast, there is evidence that the presence of peritoneal malignancy or ascites is a risk factor for port-site metastases. Vergote et al. observed 17% of port-site metastasis after laparoscopic surgery in patients with advanced ovarian cancer (11). However, port-site metastases are not lethal by themselves and are not associated with a worse outcome, as they are as chemosensitive as the underlying peritoneal disease and then generally reflect the aggressivity of the tumor (11). As a majority (22 out of 30) of port-site metastases in Vergote's series were not clinically diagnosed, it is reasonable to recommend the resection of the laparoscopic ports in a full-thickness fashion at the time of the subsequent laparotomy after a laparoscopic assessment of advanced ovarian cancer. Indeed, Heitz et al. found 47% incidence of port-site implant at the time of pathological

examination after routine resection of trocar site in 66 patients who underwent laparotomy after diagnostic laparoscopy (12). This implies that complete cytoreduction must be followed by trocar site resection. The conclusion is that port-site implant is not a complication of laparoscopic surgery in the absence of ascites or peritoneal malignancy. The early reports of port-site metastases may have been the result of faulty technique resulting in direct contamination of the abdominal wall by tumor cells.

Finally, it is logical to place all trocars in the midline when performing a laparoscopic evaluation of a clinically advanced adnexal or peritoneal cancer, to avoid muscle involvement and to easily resect the trocar sites at the time of final laparotomy. In addition, it is advised against placing the optical trocar in the umbilicus, which is a preferential site for abdominal wall tumor even in the absence of surgical scar, and would have to be fully resected at the time of final surgery.

The Issue of Intraoperative Rupture of Ovarian Masses

A recent population-based study in Norway definitively demonstrated that intraoperative rupture is associated with a worsened prognosis compared to no rupture, although to a lesser extent than spontaneous rupture (13).

The importance of the issue in laparoscopic surgery is the finding that inadvertent and unprotected ovarian cyst rupture is more frequent at laparoscopy compared to laparotomy with increased tumor size (14). On the basis of this evidence, and on concerns about the risks of peritoneal dissemination (see below), it is generally recommended that definitive surgery should be performed within 1 week in ruptured stage I cases. Although the grade of the tumor and the presence of ascites in stage I cancer of the ovary may have more important relation to survival than is rupture of the ovarian capsule at surgery, avoiding the rupture of low grade or stage IA is obviously an objective that gynecologic oncologists and general gynecologists must share, as adjuvant chemotherapy may have to be considered after extensive spillage. All pelvic masses should be considered potentially malignant, and consequently, every effort should be made to avoid rupture.

Influence of Pneumoperitoneum on Tumor Growth

On the basis of a review of experimental data, Canis et al. concluded that the risk of dissemination following laparoscopic surgery is increased when a large number of malignant cells are present (15). However, the results of various experiments are not consistent and the extrapolation of results obtained in experimental settings may be hazardous. On the contrary, using an ovarian cancer xenograft animal model, studies from Lécure et al. seems to indicate that CO₂ laparoscopy has a minor impact on visceral metastasis and survival and has no deleterious effect on tumor growth compared to gasless laparoscopy (16). In the laboratory of the first author, survival of mice injected intraperitoneally with ovarian tumor cell lines was similar after laparotomy, CO₂ laparoscopy, or Helium laparoscopy (17). Similar results have been shown in humans. Abu-Rustum et al. retrospectively reviewed patients with persistent metastatic intra-abdominal peritoneal or ovarian cancer at the time of second-look surgery. There was no difference in overall survival between patients who underwent laparoscopy or laparotomy (18). Data from animal studies suggest that the underlying immune or metabolic status of the host has a marked independent effect on tumor spread and implantation (19). Of interest are recent data showing that an 8-mm Hg pressure pneumoperitoneum is preferable to a 12-mm one. As a consequence, low pressure pneumoperitoneum may be preferable (20).

Gasless Laparoscopy in Oncologic Surgery

Due to concerns regarding the potential increased risk of tumor dissemination associated with CO₂ laparoscopy, some have advocated the use of gasless laparoscopy. The results of animal studies on peritoneal tumor growth and abdominal-wall metastasis comparing gasless laparoscopy, CO₂ laparoscopy, and laparotomy are conflicting (16,21). In contrast, a higher rate of port-site metastasis with gasless laparoscopy has been reported in some experiments (22). Although it can be used in patients for whom general anesthesia and CO₂ pneumoperitoneum are contraindicated, as it does not significantly increase the intra-abdominal pressures and since the procedure can also be performed under epidural anesthesia, gasless laparoscopy is not widely used.

Teaching and Learning Laparoscopic Surgery

Mastering laparoscopic surgery involves, apart from the skills and knowledge required to perform the same procedure by laparotomy, a variety of specific skills: translation of 3-D into 2-D perception, hand-eye coordination, ambidexterity, camera navigation, remote handling of instruments, modified tactile feedback, and fine motor skills to overcome the fulcrum effect and the lever forces. Several models can be used in resident, fellowship, or catch-up teaching programs: cadaver surgery, animal models, video trainers, and virtual reality (VR). The most realistic model is the animal model, generally the pig model (23). The cheapest is the video trainer. The “box model” training does improve surgical dexterity and economy of movement during virtual reality laparoscopy. Clevin et al. (24) used the metrics derived from a virtual reality laparoscopic trainer to assess whether a low cost box model trainer is a tool for the training of skills relevant to laparoscopic surgery. Sixteen gynecologic residents with limited laparoscopic experience were randomized to a group that received a structured box model training curriculum, and a control group. Objective parameters were registered by the computer system. The trained group showed significantly greater improvement in all performance parameters: economy of movement ($p = 0.001$), time ($p = 0.001$), and tissue damage ($p = 0.036$), confirming the positive impact of box-trainer curriculum on laparoscopic skills acquisition.

The much more expensive simulation-based training environment offers much promise as an alternative arena to cadaver, animal, or patient training. There is evidence suggesting that the skills acquired in simulation transfer to the real setting (25). In addition, it allows objective measurement of psychomotor skills. However, realism is still far from perfect, and more studies are required to strengthen the evidence base and to provide the evidence needed to determine the extent to which simulation should become a part of surgical training programs. In a review of 23 randomized trials (12 VR vs. video, 3 VR vs. VR, 4 VR vs. no or standard training, and 4 VR vs. video vs. no or standard training), Gurusamy et al. (26) identified only 3 trials at low risk of bias. VR – compared to no training – decreases the time to complete a task, increases accuracy, and decreases errors. Although the benefit of VR versus video training is not demonstrated for every criterion, a VR-trained group is more accurate than video trainer group, and shows a better composite operative performance.

As a substantial number of active gynecologic oncologists have not been trained during their fellowship, they have to catch up. Visiting surgeons may monitor established surgeons during the learning curve of an advanced laparoscopic procedure (27). Five-day–mini-residencies for urologists have been shown to result in improvement of skill tasks. However, skill acquisition is not durable if not consolidated by experience.

This is in accordance with the findings of Worley et al., who showed that surgeon volume is associated with higher complexity procedures, lower rate of conversions, less complications, and shorter hospital stay (28).

In addition, fundamental abilities (e.g., psychomotor skills, visuospatial ability, and depth perception) are critically important. In a pivotal paper of a VR trainer on this sensitive topic, Grantcharov et al. assessed the learning curve of 37 residents with limited laparoscopic experience (29). Five percent were proficient from the beginning, 70% needed 2 to 9 repetitions, 16% improved but did not reach the predefined criteria, and 8% underperformed and did not improve. The question is whether the residents lacking psychomotor skills required to perform laparoscopic surgery should be discouraged to engage in a general surgery or gynecologic oncology training involving laparoscopic surgery. It is not clear whether robot-assisted surgery is advisable to help the 16% group of low performers exposed to nonrobotic laparoscopic surgery.

As a matter of fact, the benefit of robotic surgery is mainly related to 3-D vision. Blavier et al. assessed the performance at needle-handling exercises on bench model of 40 medical students without surgical experience (30). A steeper learning curve and better performances were found for both 3-D conditions. The learning curve was steeper in 2-D robotic compared to 2-D laparoscopy. A negative impact of switching from 3-D to 2-D, and from one technique to another was observed. Evidence is given that 3-D vision is the most important factor of shortened robotic learning curve. Interestingly, students express less self-confidence in 2-D laparoscopy compared to the other modalities.

Frumovitz et al. (31) assessed in 2007 the adequacy of laparoscopic surgical training as perceived by gynecologic oncology fellows-in-training. Fellows were surveyed via mail or an internet website. One-hundred percent stated that laparoscopy is important or very important in gynecologic oncology practice. About 69% believe that their fellowship training in laparoscopy is very good or good. There is then space for improvement in fellowship training. The question of learning laparoscopic surgery before or after exposure to robotic-assisted surgery has been addressed by Öbek et al. (32). They provided evidence that beginners do better and faster with the robot in a crossover randomized experiment. Skills incompletely transfer from one modality to the other. Interestingly, skill transfer is greater from training with laparoscopy, and error rate is more decreased by laparoscopic training than by robot training (for example, no suture break occurs during robotic knot-tying after laparoscopic training). The conclusion is that dual experience is complementary and that starting with laparoscopic training is preferable.

DIAGNOSTIC AND STAGING PROCEDURES

Transperitoneal Pelvic Lymph Node Dissection

The transumbilical transperitoneal technique for laparoscopic lymphadenectomy remains the most popular approach employed by gynecologists. Early animal randomized studies have given evidence that the node yield is similar at laparoscopic and open approaches for pelvic and aortic lymph node dissections (33,34), thus justifying the spread of the technique.

The peritoneum is divided transversally between the round ligament and the infundibulopelvic ligament, which are best left undivided until the dissection is finished. An additional incision lateral to the infundibulopelvic ligament may be useful. Once the retroperitoneal space is reached, the surgeon searches for several landmarks that are, from lateral to medial, the psoas

muscle, the external iliac artery and vein, and the superior vesical artery. The paravesical space is then developed between the superior vesical artery and the external iliac vessels. The lateral wall of the bladder is retracted medially along with the superior vesical artery. This exposes the Cooper's ligament and allows identification of the obturator pedicle. The obturator nerve is the deep limit of the dissection. The nodes are separated from the obturator nerve and the external iliac from the Cooper ligament area to the bifurcation of the common iliac vessels. The nodes located between the 2 landmarks (referred to as obturator nodes) can then be firmly grasped and detached. The external iliac artery and vein are then freed from the pelvic side wall. The nodes located between the artery and vein, and the nodes located between the artery and the genitofemoral nerves are dissected. Finally, after retracting medially the external vessels, additional obturator nodes can be identified and retrieved.

Perioperative Outcomes

Querleu et al. (35) were the first to provide data describing the feasibility and safety of transumbilical transperitoneal laparoscopic pelvic dissection in 39 patients with cervical cancer stage IB to IIB. No conversion to laparotomy was required. All patients were followed for 5 years, and the 5-year survival rate was similar to the survival of a historical group of patients matched for age, stage, and therapy who underwent standard abdominal radical hysterectomy. In addition, the rate of radiation-induced bowel complications was reduced in the group submitted to radiation therapy after laparoscopic lymphadenectomy compared to the group managed by laparotomy (36).

Since then, a number of large series have documented the safety of the procedure. A similar study, comparing two groups differing only in the technique used for lymph node dissection, has recently demonstrated that laparoscopy does not have a detrimental effect on surgical or disease outcome, and can be safely applied to the treatment of early stage cervical cancer (37).

A meta-analysis of the available randomized studies comparing laparoscopy to laparotomy in endometrial cancer patients is available. The node counts after laparoscopic pelvic and para-aortic dissections, respectively, are similar in both groups of patients. However, although no heterogeneity was noted among studies regarding pelvic dissection, a significant heterogeneity was noted across studies regarding aortic dissection (38).

Benedetti et al. (39) randomly assigned to open transperitoneal, open extraperitoneal, or laparoscopic pelvic lymphadenectomy (58). All patients underwent classical radical hysterectomy. There were 168 patients who entered the study. The mean operative times were: 63, 54, and 75 minutes for transperitoneal, extraperitoneal, and laparoscopic dissections, respectively. The feasibility of the procedures, analyzed on an intention-to-treat basis was 96%, 93%, and 95%, and the average hospital stay was 5.6, 3.2, and 3.1 days, respectively.

Another recent study confirmed the early finding that the benefits of minimal-access surgery used to perform staging procedures may translate into long-term reduction in radiation-induced bowel injury (40). Staging procedures were performed on 159 patients either by open surgery (93 patients) or laparoscopy (66 patients). The site of primary tumor was the cervix in 61 patients and the corpus uteri in 98 patients. Multiple regressions revealed an independent protective effect of pretreatment laparoscopic staging against the risk of developing both grade ≥ 2 and grade ≥ 3 radiation-induced complications. The preoperative and postoperative complication rate of laparoscopic lymph node dissection has been investigated in several large series (41,42,43). The major complication and conversion rate is extremely low, inferior to 1%, in experienced hands.

Ghezzi et al. specifically evaluated the incidence of lymphoceles, lymphorrhea, and lymphedema after systematic pelvic lymphadenectomy in patients who underwent laparoscopic or

open abdominal staging for endometrial cancer (44). Overall, lymphoceles were diagnosed in 15.4% and 1.4% of patients who had open and laparoscopic staging, respectively. Symptomatic lymphoceles were more frequent after open staging than after laparoscopy. Lymphorrhea occurred in 1 and 4 patients after laparoscopic and open surgery. No difference in the incidence of lymphedema was observed.

Transperitoneal Aortic Dissection

The transperitoneal approach has been the first described technique. It mimics the open surgery approach while requiring a much shorter peritoneal incision – and virtually no mobilization of the right colon. As for every upper abdominal procedure, the surgeon stands between the patient's legs with the monitor at the head of the bed. The bowel loops are packed along with the omentum in the left upper quadrant. The dorsal peritoneum is opened alongside the axis of the right common iliac vessels, then of the lower aorta. The upper peritoneal flap is elevated along with the third part of the duodenum. The anatomical landmarks are carefully identified. The aorta and vena cava are the main landmarks. On the right side of the patient, the right ureter is identified and then moved laterally. The right ovarian vessels are identified up to the point where the ovarian vein floods into the vena cava. The ventral aspect of the aorta is dissected, and the origin of the inferior mesenteric artery is identified. The caudal aspect of the left renal vein is then identified. This step may require applying bipolar cautery and dividing the ovarian arteries to fully elevate the third duodenum. Finally, the left ureter is identified and moved laterally in the inframesenteric area. The left ovarian vein is identified in the supramesenteric area and gently moved laterally.

Since the feasibility of such an extensive dissection has been demonstrated in the early report by Querleu and Leblanc in 1994 (35), the yield of 20 nodes, with acceptable morbidity, has been reached in a large series of patients (41). When comparing the infrarenal lymphadenectomy to the inframesenteric lymphadenectomy, Köhler et al. (45) confirmed that this could be performed safely.

Extraperitoneal Lymph Node Dissection

The extraperitoneal approach is historically the first approach used to perform pelvic node sampling. It is the logical way to gain access to the aortic nodes. It has gained increasing popularity as it does have several advantages over the transperitoneal technique. Most of the advantages are related to bowel: the vision is not impaired by bowel loops, it is not influenced by the presence of bowel adhesions, and it creates less *de novo* adhesions (46,47), which is critical for patients/candidates for radiation therapy. The disadvantages are a smaller space, a higher risk of lymphoceles as a result of the absence of intraperitoneal drainage, an increased reabsorption of CO₂, and the lack of assessment of the peritoneal cavity, which is mandatory in gynecologic oncology patients. The latter is overcome by the routine use of an associated intraperitoneal diagnostic laparoscopy.

Extraperitoneal Aortic Node Dissection

In addition to the advantages mentioned above, the extraperitoneal route is more ergonomic for aortic dissection, as the surgeon stands lateral to the patient and works in a horizontal plane, watching the screen placed on the other side of the patient. The left lateral approach is preferred to the right-sided approach for several reasons: the upper part of the dissection, which is the left infrarenal area, is more easy to reach; at the same time, it is the preferred site of node metastasis; in addition, the key areas of the right side, including the precaval and laterocaval nodes, can be

easily dissected from the left side. After preparation of the space (see below), an 8- to 10-mm Hg pressure is enough to maintain the working space.

Extraperitoneal aortic dissection has been first reported by Vasilev and McGonigle in a small series (48). The mature technique has been fully described in earlier papers from French groups (49). An extraperitoneal approach to the aorta is begun by using a 3-cm incision made in the left lower quadrant, medial to the iliac spine. The successive layers of the abdominal wall are transected, including the parietal fascia, leaving the parietal peritoneum intact. Using finger dissection, the peritoneal sac is elevated off the underlying structures. A 10-mm incision of the anterior axillary line and a 5-mm incision in the left upper quadrant are made to accommodate corresponding blunt trocars that are inserted under finger guidance in the extraperitoneal space. A second ancillary trocar is introduced in the infracostal area in the midaxillary line. A laparoscopic balloon trocar is then introduced in the first incision. It will accommodate the endoscope. The extraperitoneal space is inflated while the peritoneal cavity is exsufflated. The initial landmarks (psoas muscle, left common iliac artery, and left ureter) are identified; the initial dissection plane is found between the ureter and the common iliac artery. The space is developed by elevating the peritoneal sac along with the ureter. Access is gained to the presacral area and then to the right common iliac area. Further development is obtained in the cephalic direction by clearing the psoas muscle and the lateral aspect of the left common iliac artery and of the aorta. The inferior mesenteric artery and the left renal vein are generally identified by following the left ovarian vein up to the point where it ends. The nodes are then separated from the vessels and from the sympathetic chain by a combination of hemostasis and section. Multifunction instruments are more adapted, as they avoid changing instruments and allow to overcome the fact that only two ancillary instruments can routinely be placed in the narrow retroperitoneal space.

Sonoda et al. (50) reported on a large series of 111 patients with locally advanced cervical cancer who underwent surgical staging. The mean duration of the procedure was 157 ± 46 minutes and the average number of nodes was 19. The mean postoperative stay was 2 days. Perioperative complications occurred in 14 patients. The majority of these complications were symptomatic lymphoceles that occurred in 11 patients: 8 of these lymphoceles were drained under radiologic guidance, 2 required a catheter placed under anesthesia, and 1 required laparoscopic drainage. The rate of symptomatic lymphoceles was later reduced by opening the peritoneum at the end of the procedure ("marsupialization" of the peritoneum) to drain the retroperitoneal fluid into the peritoneal cavity.

The typical indication for extraperitoneal aortic dissection is the patient with locally advanced cervical carcinoma. Knowledge of the status of the aortic nodes allows tailoring of the radiation therapy fields. With this indication, common iliac nodes are generally removed along with the aortic nodes. The potential benefit of surgical staging of locally advanced cervical cancer is based on the lack of sensitivity of positron emission tomography in the identification of micrometastases less than 5 mm (51), knowing that the group of patients with small lymph node metastases is the most likely to benefit from surgical removal of nodes (52). However, the indication and extent of the dissection, including or not the supramesenteric nodes, is still controversial (53).

The finding that this approach is more feasible than the transperitoneal approach for aortic dissection, particularly in obese patients, has led to the adoption of the extraperitoneal route as an elective choice in the staging or restaging of obese endometrial or ovarian cancer patients. In such patients, the aortic dissection is performed retroperitoneally following which the other steps of the procedure are performed transperitoneally. To achieve this, the extraperitoneal trocars are replaced in the peritoneal cavity.

Extraperitoneal Pelvic Node Dissection

Laparoscopic pelvic lymphadenectomy can be performed using the direct extraperitoneal approach. Historically, this approach was the first application of panoramic surgical endoscopy in oncology. This approach starts with a blind digital preparation of the preperitoneal space or with the use of direct vision trocar devices. A midline suprapubic access or an infraumbilical access may be used. Ancillary trocars are placed in the preperitoneal space.

This approach which has no definitive benefit over the transperitoneal approach while featuring all the shortcomings of the extraperitoneal approach, and which is limited to the pelvic area, has been largely abandoned in the gynecologic field. However, it is still used in urologic indications, with similar results compared to the transperitoneal approach (54) and has been recently rediscovered more than 20 years after having been pioneered by Dargent (55). It may be useful in cases where the pelvic cavity is not accessible or not easily accessible such as in pregnancy more than 16 weeks or when severe postoperative adhesions are present.

An innovative variant has been described recently using the same left lateral approach as used to perform an aortic dissection (56). The method may be useful to retrieve pelvic nodes when deemed necessary at the time of surgical staging of advanced cervical cancer, or to shorten the transperitoneal step of the surgical staging of endometrial or ovarian cancer. However, but in some favorable cases, it is limited to the left pelvic area.

Laparoscopic Identification of Sentinel Nodes

The laparoscopic identification of sentinel nodes can be considered as the symbol of the trend toward minimizing the surgical trauma of staging gynecologic malignancies and optimally using the possibilities of laparoscopic surgery. The original goal of the sentinel node concept was to avoid a complete lymphadenectomy in node-negative patients and, in some circumstances, in node-positive patients as well. The laparoscopic approach is fully adapted to the objectives of a pre-therapeutic workup procedure: defining the extent of disease and commensurate therapy without exposing the patient to an excessive risk; in addition, the magnification associated with the laparoscopic view is ideal to identify minute lymphatic channels. The development of endoscopic gamma probe has made possible the use of the combined (isotopic and colorimetric) assays that are mandatory to increase the accuracy of the method.

Technically, the identification and retrieval of pelvic sentinel nodes involves several steps. Intracervical injection of radiolabeled colloid is performed before the surgery. Planar or Single-photon emission computed tomography-computed tomography (SPECT-CT) imaging is a useful tool in locating sentinel nodes, particularly the nodes located outside the field of usual pelvic lymphadenectomy (57,58,59). Injection of blue dye is performed at the time of surgery. The 4-quadrant approach is being gradually replaced by a 2-quadrant approach that reduces the risk of injecting the pouch of Douglas. After having established the laparoscopic view, the surgeon uses the gamma-probe to globally locate nodes before incising the peritoneum in front of the "hot" node. Blue lymphatic channels may also be identified occasionally below the peritoneum. The peritoneum is then incised. On either side, the node closest to the cervix (the closest at isotopic identification, the first to be connected to a blue channel coming from the cervix) is bluntly dissected. Special care must be taken not to injure adjacent structures, as the sentinel node technique does not imply identifying at first the major anatomical landmarks of the area.

Several systematic reviews (60,61), 2 prospective multicenter studies (62,63), and the recent report of pioneers in the

field (64) have established the diagnostic value of sentinel node identification in the staging of uterine cancer. Detection rate is 97% to 99% using the combined technique (60,64). Laparoscopic sentinel node identification is highly reliable, with 100% sensitivity, using the full pelvic dissection as the gold standard. However, definitive conclusions can be drawn only when sentinel nodes are identified bilaterally (60,64). This implies that full dissection remains mandatory on the site where no sentinel has been identified. The sentinel node concept does not apply to massive involvement of the nodes, stressing the fact that careful preoperative imaging is required to identify patients with grossly enlarged nodes. Interestingly, 17% of sentinel nodes are found in “aberrant” locations and would have been missed by a standard lymph node dissection. Frozen section of sentinel nodes is of value only if positive, as over 40% of positive nodes are identified after “ultrastaging” involving serial sections and immunohistochemistry in cervical cancer (64). Interestingly, of the metastatic sentinel lymph node (SLN) metastases not identified on frozen section in Roy et al. series, only one measured more than 2 mm (2.9 mm), seven measured between 0.4 mm and 2 mm (micrometastases), and two had isolated tumor cells only. The same finding has been reported in endometrial cancer patients (63). This finding is not a flaw of the sentinel node concept in uterine cancer, but a shortcoming of the frozen section examination. Thus, awaiting the development of novel intraoperative imaging techniques such as fluorescence of tumor cells (fluorescence of lymph channels is not a solution), a reasonable strategy may include: (a) laparoscopy with sentinel node biopsy, (b) frozen sections of the sentinel nodes, and (c) systematic dissection if the frozen section is negative. In the cases where either the sentinel node biopsy or other nodes have metastasis, aortic node dissection is performed during the same operative session and chemoradiation can be proposed only to avoid combining radiation therapy and surgery in the same patient after laparoscopy.

The concept of laparoscopic sentinel node has first been developed in cervical cancer, as a tool to select patients most suitable for surgical management. In low- and intermediate-risk endometrial cancer, the rationale is different as the need for lymph node dissection is controversial. Sentinel node could be a midterm between no dissection (leaving the small proportion of node-positive patients) and full dissection (adding a useless procedure in the majority of node-negative patients). In addition, ultrastaging of the sentinel nodes using intracervical injection of dye and colloid detects micrometastases otherwise undiagnosed by conventional histology even in patients considered at low risk on the basis of grade and depth myometrial invasion (63). The question of alternative injection sites, hysteroscopic or fundic, in endometrial cancer patients has been addressed (65,66), without evidence of benefit of the more demanding and less practical modalities.

Laparoscopic Diagnostics of Pelvic Masses

The management of early ovarian cancer and borderline tumor of the ovary will be addressed in a later section. The topic of this section is to explore the advantages – diagnosis and management of benign masses – and the drawbacks of introducing laparoscopy in the flowchart of the assessment of a pelvic mass. The laparoscopic management of pelvic masses significantly reduces the length of hospital stay, operative morbidity, and overall postoperative recuperation time. Despite careful preoperative evaluation, it appears inevitable that some of those masses will turn out to be malignant. Proper management and adherence to strict surgical guidelines are very important in achieving optimal results.

Large series reported that among all patients approached laparoscopically for pelvic masses, the overall rate of malignancy

is low. The rate varies greatly among the studies according to the preoperative selection criteria used and the study design. In 1994, Canis et al. (67) published an extensive, retrospective 12-year analysis with long-term follow-up of 757 patients from 1980 to 1991. The rate of inadvertent malignancy was 2.5% (19 of 757), including 12 borderline and 7 invasive cancers. Additionally, 27 masses were falsely diagnosed as malignant (3.6%), which means that these patients had an unnecessary laparotomy. Canis et al., based on that experience, considered laparoscopic management of pelvic masses to be safe and reliable. The findings of this early publication have been consistently confirmed in several studies. Leng et al. retrospectively reviewed a series of 2,083 patients laparoscopically managed for adnexal masses. Sixteen patients had a malignant or borderline tumor, 14 of them were diagnosed intraoperatively. No adverse outcome related to laparoscopic diagnosis was reported in this study (68). A randomized controlled study on 102 patients comparing laparotomy to laparoscopy showed that inadvertent cyst rupture was frequent in both groups and operative time was comparable. The laparoscopic approach was associated with significant reductions in operative morbidity, postoperative pain, required analgesia, hospital stay, and recovery period (69).

However, the surgeon must keep in mind that failure to diagnose malignancy; underestimation of the extent of disease; tumor spillage from rupture of the masses; inability to perform complete staging (implying another surgery for the patient); and, most important, long delays before a staging procedure or definitive treatment can adversely affect the ultimate prognosis of the patient (70). Maiman et al. (71) surveyed Society of Gynecologic Oncologists (SGO) members with regard to their management of ovarian neoplasms later found to be malignant. The response rate from members was 42% and 42 cases of ovarian malignancy were reported. In that survey, immediate staging had been performed in 17% of cases, delayed in 71% (median, 36 days), and not performed in 12%. The authors raised significant concerns with regard to the negative outcome of the significant number of patients who were not restaged and to the delay between the initial procedure and the definitive treatment. They concluded that delays of more than 4 weeks had a negative impact on patient outcome. Blanc et al. (72,73) conducted a similar multi-institutional French survey and recorded 5,307 ovarian lesions treated laparoscopically, of which 1.4% were malignant. Staging of cancer cases was performed immediately in 25% of the cases, delayed in 58% (median, 78 days), and not performed in 16%. In those who had delayed staging, 22.4% were upstaged. Kindermann et al. (74) also sent a questionnaire to 273 German departments of obstetrics and gynecology with a response rate of 46%. They collected a total of 192 ovarian cases managed laparoscopically. Capsule rupture and tumor morcellation with intra-abdominal spillage occurring at laparoscopy was associated with spread of disease and port-site metastases identified at staging laparotomy. Endoscopy bags were used in only 7.4% of ovarian cancer cases. Leminen and Lehtovirta (75) reported on 8 patients who had their staging laparotomy after laparoscopic surgery within a mean of 17 days (range, 7 to 29). In 4 patients, the disease had spread from a localized to an advanced stage. The authors concluded that laparoscopic surgery of ovarian masses later found to be malignant can cause considerable and rapid spread of the disease. Lehner et al. (70) sent a questionnaire to all gynecology departments in Austria regarding laparoscopic management of ovarian masses later found to be malignant. They found that patients in whom definitive surgery was delayed more than 17 days were more likely to be upstaged (odds ratio of 5.3 for borderline tumors and 9.2 for invasive cancers).

A series of 141 patients undergoing laparoscopic surgery for a pelvic mass looked at the accuracy of frozen section to guide the surgical management. This study showed that the frozen section diagnosis was accurate in 95.5% of benign tumors, 77.8% of borderline tumors, and in only 75% of cancers (76).

The accuracy of the frozen section (FS) is also size-dependent: for masses larger than 10 cm, FS becomes less reliable (77). These results confirm that FS is a useful but inconsistently reliable tool to guide the intraoperative management. Thus, an alternate effective policy consists in removing every adnexal mass without spillage or contamination of the abdominal wall, waiting for definitive pathology and then planning whenever necessary for definitive laparoscopic staging and management of the disease.

The concept that patients with a suspicious pelvic mass should necessarily undergo laparotomy has been challenged. A diagnostic laparoscopy can be performed regardless of the ultrasonographic appearance of the pelvic mass, although an immediate laparotomy is recommended for staging and management of obvious cancer cases at laparoscopy. Laparoscopic management of high-risk pelvic masses can be successfully performed in an oncology referral population if there is expertise in operative laparoscopy, availability of immediate and accurate pathologic evaluation, and appropriate further treatment where indicated (78). In some cases, having an onsite oncologist skilled in advanced laparoscopic procedures allows laparoscopic completion of the staging procedure. However, when skilled assistance is unavailable, it is best to terminate the laparoscopic procedure after a cancer diagnosis and to promptly refer the patient for definitive surgery. Laparoscopy for the management of pelvic masses can eliminate the need for unnecessary laparotomy in most cases. Statistically, the majority of them will be benign and can be adequately managed laparoscopically. However, surgeons should be technically meticulous to minimize the risk of ovarian cyst rupture and spillage, and specimens should always be retrieved intact through an endobag to reduce the risk of trocar-site metastasis.

In a series reported by Havrilesky et al., the ovarian malignancies discovered at the time of laparoscopy for pelvic masses were managed laparoscopically and this was not associated with an adverse outcome (79). Lécuru et al. found no deleterious influence of laparoscopy as first surgical access on outcome of patients with early-stage ovarian cancer (80).

Abdominal Staging or Restaging Procedures

Working in the upper abdomen generally requires using the same position of the surgeon and the same placement of trocars adopted to perform a transperitoneal aortic dissection: trocars are placed lateral to the umbilicus, and the surgeon stands between the legs of the patient. Some advise to place the endoscope in the suprapubic area. Alternatively, the surgeon can use the position adopted to perform an extraperitoneal aortic dissection: 2 trocars are placed in the left flank, and the surgeon stands on the left side of the patient, working horizontally. This position is quite ergonomic, and can be used to perform an omentectomy after an extraperitoneal aortic dissection, after replacement of the trocars in the abdominal cavity.

Taking peritoneal biopsies is straightforward. A grasping forceps creates a fold on the peritoneum. The fold is incised, taking care not to injure underlying structures. The peritoneal flap is then elevated and excised. The same technique is used to perform biopsies of undersurface of the diaphragm. Once the diaphragmatic peritoneum is incised, the pressure of the CO₂ contributes to develop the space between the peritoneum and the muscle fibers. There is usually no need for hemostasis or specific instrumentation.

Omentectomy is a mainstay of peritoneal staging. Infrahcolic omentectomy is the standard diagnostic procedure. The procedure is straightforward using the modern multifunction instruments that allow to grasp, to apply hemostasis, and to cut. Controlled bipolar energy with cutting or ultrasonic shears can indifferently be used. Additional bipolar cautery or clip may

have to be used to control bleeding. The omentectomy generally starts at the left splenic flexure. The transverse colon is identified by elevating the omentum. The assistant constantly stretches the omentum to constantly identify the angle between the omentum and the transverse colon. The cutting instrument is used parallel to the caudal aspect of the transverse colon and gradually detaches the omentum from the colon, taking care not to injure the transverse colon. The omentum is then placed either in a bag, or left in the pouch of Douglas if a hysterectomy is planned.

Infragastric omentectomy is less frequently performed laparoscopically. It requires two additional steps: separating the transverse colon from the gastrocolic ligament, and controlling the vascular supply at the level of the greater curvature of the stomach. Separating the transverse colon is achieved by cutting the peritoneal layer attaching the omentum to the transverse colon, then elevating the omentum from the mesocolon while entering the lesser sac. Controlling the vessels of the greater curvature of the stomach is best achieved using blocking clips (Hem-o-lok) inserted via a 10-mm instrument. Incidentally, a similar technique is used to prepare omental flaps when necessary.

The technique of appendectomy is beyond the scope of this chapter. Briefly, the appendix is grasped and elevated, the meso-appendix is coagulated and cut, the base of the appendix is tied using a loop or a blocking clip, and the appendix is divided.

Laparoscopic Assessment of Advanced Adnexal or Peritoneal Malignancy

Assessment of Resectability

The technique described in this section refers to the assessment of the peritoneal disease in patients with advanced ovarian cancer characterized by ascites, carcinomatosis, and omental cake, to take biopsies and select the patients for optimal surgical debulking by laparotomy. Unfortunately, there is no perfect tool to determine preoperatively whether patients can be optimally debulked surgically, or be proposed neoadjuvant chemotherapy. CT scan can be used for this purpose, and biopsies under radiologic guidance may be performed. However, CT scan may underestimate the extent of the disease, in particular the extent and location of carcinomatosis, and biopsy under radiologic guidance is not always feasible. Other malignancies, particularly of gastrointestinal origin (such as colon, pancreas, stomach, and others), or rare peritoneal malignancies (mesothelioma) can mimic adnexal or peritoneal cancer. Definitive pathologic diagnosis is critical before initiation of any chemotherapy. This is why laparoscopy has become a valuable diagnostic tool in the workup of advanced peritoneal disease.

The diagnostic laparoscopic procedure can have some pitfalls: first, the presence of a large amount of ascites may lead to a reduced visibility; second, the gastrointestinal (GI) anatomy can be distorted, or the colon and/or small bowel may be adherent to the anterior abdominal wall or omentum, which may increase the risk of bowel injury. The entire abdominal cavity may not be accessible to laparoscopic vision. Lastly, the issue of trocar-site implantation remains controversial, particularly in patients with adenocarcinoma, ascites, and carcinomatosis (see section on Port-site metastasis and risk of tumor dissemination). Technical details have been provided in this section concerning port-site metastases: placing the trocars in the midline, preventing port-site metastases, and excising the trocar sites at the time of laparotomy are mandatory.

Diagnostic accuracy essentially depends on the quality of sampling. Prediction of resectability is a much more complex question, as it depends on the skills and aggressivity of the surgeon. Angioli et al. reported on 87 patients with advanced ovarian cancer who underwent first a diagnostic open laparoscopy (81). In 61% of patients, optimal cytoreductive surgery was deemed possible and those patients underwent a laparotomy

and debulking surgery. The goal was achieved in 96% of cases. Conversely, in 39% of cases, optimal debulking appeared impossible and the first cycle of chemotherapy was quickly initiated the day following laparoscopic surgery, which is an obvious advantage of minimal access surgery and a possible prevention of the development of port-site metastases. The authors concluded that diagnostic open laparoscopy is a valid diagnostic tool to evaluate the extent of disease and avoids unnecessary laparotomies in patients where optimal debulking cannot be accomplished. Consequently, Fagotti et al. proposed a simple laparoscopy-based scoring system to estimate the chances of achieving optimal cytoreduction based on the presence of an omental cake, peritoneal carcinosis, diaphragmatic carcinosis, mesenteric retraction, bowel infiltration, stomach infiltration, and liver metastases. Each parameter was assigned 2 points if present. A score of greater than 8 predicted a suboptimal surgery with a specificity of 100%, a positive predictive value of 100%, and a negative predictive value of 70% (82). Other investigators later performed an external evaluation (83) that provided an external validation of Fagotti's score and showed that a simplified score (excluding omental cake and peritoneal carcinomatosis) could also be used. Fagotti et al. tested the ability of a fellow to accurately use the scoring system (84).

Laparoscopy still may be a valuable approach to avoid incomplete interval debulking surgery in patients deemed inoperable of the initiation of therapy, and in whom resectability is still questionable after completion of three cycles of chemotherapy. The results of this policy have been reported by Fagotti et al. in 2010 on 98 patients, resulting in a rate of exploratory laparotomies as low as 10% (85).

Second-Look Procedure

Second-look surgery – systematic surgical and pathologic assessment of the abdominal and pelvic cavity in patients who are clinically without evidence of disease – in advanced ovarian cancer has lost popularity. However, the model has allowed to establish the practical value of laparoscopic assessment of the peritoneal cavity. Husain et al. reported that the rate of negative evaluations and the rate of recurrences in patients with negative laparoscopic second looks are equivalent to those described in studies of second-look assessment by laparotomy (86). Conversely, in a prospective comparative study, a French group found the laparoscopic second-look evaluation to be suboptimal when compared to the abdominal approach, mainly because of the presence of adhesions which appeared to limit the thoroughness of the evaluation (87). In that study, the positive predictive value was 100%, but the negative predictive value was 86% (2 false-negative cases). Clearly, if residual tumor implants are readily confirmed at laparoscopy, then a laparotomy can be avoided in those patients. In patients with negative laparoscopic evaluation, it remains uncertain if laparotomy is more accurate, particularly in patients with diffuse adhesions. Littell et al. reported on 99 patients who had achieved a complete clinical response following first-line chemotherapy and underwent second-look surgery (88). Nearly 70% had a negative second-look laparoscopy and were converted to a planned laparotomy, whereas 32% had positive findings at laparoscopy and thus were spared a laparotomy. In that study, the negative second-look laparoscopy predicted a negative laparotomy in 91% of the cases. The authors concluded that the small increase in sensitivity offered by laparotomy does not warrant the increased morbidity. A pilot study from the Memorial Sloan-Kettering demonstrated that the laparoscopic approach results in less morbidity, shorter operating time, shorter hospital stay, less blood loss, and lower total hospital charges (89). Husain et al. later concluded, in a series of 150 cases, that the complication rate of the laparoscopic approach is low and that it is a safe approach even in patients who had a prior abdominal surgery (86).

LAPAROSCOPIC OR LAPAROSCOPICALLY ASSISTED SURGICAL MANAGEMENT PROCEDURES

In this section, only the surgical procedures required for the management of primary gynecological malignancies will be detailed. Lymph node dissection and other procedures associated to the comprehensive management of gynecologic malignancies have been described above. The extent and indications of specific surgical procedures, and the extent of lymph node dissection are beyond the scope of this chapter. It is assumed that the reader masters these techniques enough to be able to provide the patient a standard of care consistent with the current guidelines.

Surgical technique

Simple hysterectomy

“Simple” – as opposed to radical – hysterectomy and bilateral salpingo-oophorectomy remains the cornerstone for the treatment of endometrial cancer. In addition, the trend toward a reduction of radicality in microinvasive or low-volume early cervical cancer has put simple hysterectomy in the armamentarium for the surgical management of cervical cancer. Total hysterectomy has been traditionally performed through an open approach to completely assess the peritoneal cavity and perform lymph node sampling or lymphadenectomy. Vaginal hysterectomy only has been used in the management of endometrial cancers in patients with multiple comorbidities. However, the vaginal route does not allow for the evaluation of the peritoneal cavity and the retroperitoneal lymph nodes, which has been made possible by the introduction of laparoscopic lymphadenectomy. For that reason, MIS has become increasingly popular in the management of gynecologic malignancies to the point that it has become a standard in surgery for endometrial cancer (90).

From a technical point of view, knowing that the uterus is invariably retrieved vaginally, the whole range of combinations of laparoscopic and vaginal approach (laparoscopically assisted vaginal hysterectomy) is available to the surgeon. Theoretically, several combinations are available: laparoscopic staging only, laparoscopic staging with management of the upper pedicles, laparoscopic staging with management of the upper pedicles and of the uterine arteries, laparoscopic hysterectomy followed by closure of the vaginal cuff through a vaginal approach, and full laparoscopic hysterectomy. However, considering the shortcomings of shifting from laparoscopic to vaginal approach, which requires changing surgeon's and patient position, and an additional set of instruments, full laparoscopic hysterectomy has gained more acceptance. Only patients not suitable for laparoscopic hysterectomy for whatever reason will benefit from an additional vaginal approach. Even when the vaginal approach is elected, it is made much safer and easier, particularly in obese patients, if the infundibulopelvic pedicles have been divided. The conclusion is then that practically, only two logical options are opened to surgeon's choice: (a) laparoscopic staging and management of upper pedicles followed by vaginal hysterectomy and (b) full laparoscopic hysterectomy.

Full Laparoscopic Hysterectomy

The full laparoscopic hysterectomy is mastered by many modern gynecologists. The mainstay of the technique, both cheap and reliable, is the use of monopolar energy for the division of the peritoneum and vagina and of bipolar cautery for the hemostasis of the main pedicles. It is substantially facilitated by the use of a cul-de-sac presentator. Although reservations about the use of

these instruments have been raised, no objective detrimental effect on cancer outcome has been demonstrated. In addition, at least one needle holder is necessary to complete the closure of the vagina laparoscopically.

The round ligaments are typically divided using monopolar cautery. Preventive hemostasis of infundibulopelvic ligaments is achieved using bipolar cautery, or blocking clips, or any other adapted device. The only potential danger is the ureter, which is running at a distance from the ovarian vessels if the corresponding adnexa is grabbed and firmly moved medially to stretch the infundibulopelvic ligament. The peritoneum of the posterior leaf of the broad ligament is then divided in the direction of the torus uterinus, taking care to incise the peritoneum only and not to injure the underlying vessels. The uterine insertion of the uterosacral ligaments is then cauterized and cut. The peritoneum of the ventral part of the pouch of Douglas is opened. The peritoneum of the vesical fold is then incised and the vesicouterine septum is developed, down to the point where the anterior vaginal cul-de-sac delineated by the cul-de-sac presentator is fully separated from the bladder. The uterine pedicles are then visible in either broad ligament. The ascending branches are cauterized and cut slightly above the uterine isthmus. The last attachments of the uterus are then cauterized and cut medial and caudal to the uterine vessels. The lateral cul-de-sacs, featuring their characteristic white color, are freed from the surrounding tissues. The vagina is incised anteriorly and then grabbed. The vaginal incision is completed using a monopolar hook. The uterus is delivered. Hemostasis is checked and completed if necessary using bipolar cautery. The vaginal cuff is closed by a continuous suture running from one angle of the vagina to another.

Laparoscopic Management of the Upper Pedicles and Vaginal Hysterectomy

This option is more appealing to surgeons who have been trained in vaginal surgery. The management of the infundibulopelvic and round ligaments is straightforward even for any modern gynecologic surgeon, and does not require specific training. The laparoscopic management of the upper pedicles can be occasionally complemented by the division of the posterior leaf of both broad ligaments, thus favoring the vaginal mobilization of the uterus, and by the coagulation of the origin of the uterine arteries that is routinely identified at the time of lymph node dissection.

The technique of vaginal hysterectomy is beyond the scope of this textbook. The uterine cervix is firmly grabbed using grasping forceps. The full thickness of the vagina is incised. The pouch of Douglas is entered, and the vesicouterine space is developed. Interestingly, the remaining steps can be completed using the instruments and the technique of laparoscopic surgery: serial bipolar coagulation and division of the attachments of the cervix, the isolation and placement of a blocking clip on each uterine artery mimic in a retrograde way the technique of laparoscopic hysterectomy (91). Obviously, both vaginal and laparoscopic techniques are “minimally invasive” and are complementary. The patient highly benefits from any combination of both techniques, and the surgical technique by both approaches is improved by the dual training.

Perioperative Outcomes: Evidence-Based Benefits of Laparoscopic Surgery

Simple hysterectomy technique and results are extensively documented in the literature addressing benign gynecology procedures. It conveys obvious advantages over the open procedure. With exceptions, the choice should be made between the laparoscopic and the vaginal approach. When the choice is open, with a patient suitable for both approaches, and a surgeon trained in both techniques, full laparoscopic hysterectomy may be the preferable approach, as it has been found to be associated with

less postoperative pain in a randomized trial (92). However, vaginal hysterectomy has a shorter operating time, and possibly less complications, as evidenced in another randomized trial in women with benign uterine disease (93). This is true even in patients generally deemed to present a contraindication of vaginal surgery (94).

In gynecologic oncology, most of the literature refers to the combination of hysterectomy and lymph node dissection in the surgical management of endometrial cancer, thus making the analysis of perioperative data concerning hysterectomy by itself more difficult. However, high level evidence in favor of laparoscopic surgery including data from controlled studies is available. Interestingly, one of the studies from the Netherlands compared only hysterectomy in a cohort of endometrial cancer, with no interference of lymph node dissection (95).

Hauspy et al. recently reviewed the literature until January 2009 (96). They reviewed 23 articles: 5 were randomized controlled trials (RCTs), 4 were prospective reviews, and 14 were retrospective reviews. More recently, a meta-analysis of the available randomized trials has been published (38). Estimated blood loss and hemoglobin or hematocrit change was consistently less after laparoscopy in the six studies where they were reported (95–101).

After combining the data from all of the RCTs included in their meta-analysis, Zullo et al. found that intraoperative complications rates were not different between laparoscopy and laparotomy (RR, 1.25; 95% CI, 0.99–1.56) without significant heterogeneity across the studies (98). They found a significant advantage of laparoscopy over laparotomy in terms of postoperative complications (RR, 0.71; 95% CI, 0.63–0.79) with significant heterogeneity across the studies. In a recent study, a significantly higher proportion of patients in the open surgery group experienced adverse postoperative grade 3 or higher (23.2% vs. 11.6%) (102).

The largest randomized trial is the LAP2 study (99) that was designed to compare laparoscopy versus laparotomy for comprehensive surgical staging and management of stage I to IIA uterine cancer including hysterectomy, salpingo-oophorectomy, pelvic cytology, and pelvic and paraaortic lymphadenectomy. Patients were randomly assigned to laparoscopy ($n = 1,696$) or open laparotomy ($n = 920$). A significantly longer operative time (204 vs. 130 minutes) was observed in the laparoscopy group. Intraoperative complication rates were similar. Laparoscopy had significantly fewer moderate to severe postoperative adverse events than laparotomy (14% vs. 21%). Hospitalization of more than 2 days was significantly lower in laparoscopy versus laparotomy patients (52% vs. 94%). Although pelvic and paraaortic nodes were not removed in 8% of laparoscopy patients and 4% of laparotomy patients ($p < 0.0001$), no difference in overall detection of advanced stage was seen. The study has a major shortcoming related to its multicentric design: a high conversion rate. About 25.8% of patients assigned to the laparoscopic arm were converted to laparotomy, reflecting the learning curve of some investigators, particularly for node dissection. However, as it is likely that further training would have resulted in even better results of laparoscopic surgery, this does not weaken the conclusions of the paper. This study gives evidence that laparoscopic surgical staging for uterine cancer results in fewer complications and shorter hospital stay.

A few recent open series specifically addressed the issue of complications. Tinelli et al., in 2011, compared the complication rates of laparoscopic and open surgeries in a multicenter series of 226 women with early stage endometrial cancer (103). Patients underwent total hysterectomy and pelvic dissection. One patient of the laparoscopy group had an uretero-vaginal fistula and another patient had a ureteral stricture temporarily treated with a stent. One patient of the laparoscopy group had a bowel perforation due to dense adhesions with the peritoneum under the umbilicus, resolved with a bowel resection and an

end-to-end anastomosis. In 3 patients of the laparoscopy group a vaginal cuff dehiscence was observed and in one case a pelvic lymphocyst was reported. Barnett et al., in 2011, retrospectively compared a group 107 women patients who underwent laparoscopy with a group of 269 patients matched on age and body mass index (104). Adverse event rates were nonsignificantly different between cohorts (37% laparoscopy vs. 43% laparotomy). Laparoscopy had higher unexplained rates of mild sensory peripheral nerve deficit (5% vs. 0%) and lymphedema (7% vs. 1%), whereas laparotomy had higher rates of cellulitis (16% vs. 7%) and open wound infections (9% vs. 2%).

Palomba et al. reported in 2012 on 1012 endometrial cancer patients operated between 2000 and 2010 in 6 Italian centers (105). Although retrospective, the study reflects the use and benefits of laparoscopic surgery in clinical practice out of the experimental setting of pioneering centers. Overall, 403 patients were managed laparoscopically while 609 had open procedures. Advanced stage, grade 3, and papillary serous subtypes were more often managed by laparotomy. Interestingly, the rate of laparoscopies increased in all centers throughout the time of the study. Feasibility in the laparoscopy group was 86.8%. Operative time was significantly longer in the laparoscopy group (199 vs. 135 minutes). The overall rate of pelvic and aortic dissection and the number of retrieved pelvic and aortic nodes were similar in the two groups. Complication grade was higher in the laparotomy group. Blood loss was less in the laparoscopy group. Recurrence and survival rates were similar in both groups. This study has several flaws: retrospective and unbalanced by nature (731 patients were excluded from the study because of lack of relevant pathologic and clinical data), it encompasses a long period of time with a trend toward the development laparoscopic surgery in all centers. Stage I endometrial cancer is indisputably an elective indication for laparoscopy, stage II patients must be operated in tertiary centers, and the rationale of surgery in clinical stage III is not different from the rationale adopted in ovarian cancers, with similar reservations.

A theoretical pitfall to laparoscopic management of endometrial cancer is the potential for retrograde seeding with the use of a uterine manipulator. On this basis, some surgeons seal the fallopian tubes before beginning the hysterectomy. However, whether or not the incidence of positive peritoneal cytology is higher after laparoscopic surgery is controversial (106). This is probably a nonissue, as any intrauterine diagnostic procedure is associated with retrograde reflux of endometrial cancer cells, and since the presence of isolated cells is not associated with a higher risk of recurrence (107).

Cost Issues

A systematic review of cost issues based on randomized trials is available (108). Analysis was performed on 2,226 patients, of which 1,013 were managed laparoscopically. While the total direct costs in the laparoscopy group (\$63,997) were marginally higher than the abdominal surgery group (\$60,114), the total indirect costs of the laparoscopy group (\$1,609) were substantially lower than in the abdominal surgery group (\$3,139). The authors concluded that the shorter hospital stay and a lower complication rate in the laparoscopy group compensates for the increased procedure costs but called for further research with a broader cost perspective. The same team later published on the economic aspects of the Dutch randomized study. The median utility scores were comparable between laparoscopy and laparotomy at 3 months. The increased intraoperative cost of laparoscopy, reflecting the longer duration of surgery and the use of disposable instruments, was compensated by a less costly postoperative hospital stay (+ \$1,129 vs. - 1,350, respectively) (109).

In a societal perspective approach, Barnett et al. found laparoscopy (\$10,128) as the least expensive approach followed by robotic and (\$11,476) and open hysterectomy (\$12,847) (110).

They also found that in the hospital perspective, laparoscopy was least expensive compared to laparotomy only if hospital stay after open surgery was more than 2.9 days (109).

Conclusion

There is thus definitive evidence of the short-term benefit and cost-effectiveness of laparoscopic hysterectomy in gynecologic cancer patients. This includes patients with comorbidities, obesity, or advanced age. The issue of the obese patient will be addressed in a specific section later in the chapter (The Case of The Obese Patient). Regarding comorbidity, Tozzi et al. found that patients with serious comorbidities benefit the most from laparoscopy (111). The case of the elderly patient has been addressed in the gynecologic oncology literature. Siesto et al. reported a series of 48 patients older than 65 years (112). This group of patients was comparable to younger patients in operative time, blood loss, need for blood transfusions, nodal count, and intraoperative and postoperative complications. They concluded that in the absence of absolute anesthesia contraindications, laparoscopy is feasible and safe in older women with endometrial cancer. As the group of older patients was more frequently upstaged than the group of younger patients, they stated that comprehensive surgical staging should be offered, regardless of age, to avoid understaging and to optimize treatment strategies.

The major shortcoming of laparoscopic surgery is increased operative time. However, operative time is directly dependent on the surgeon's factor. Interestingly, in the first study involving laparoscopically assisted vaginal hysterectomy by surgeons experienced in vaginal and laparoscopic surgery, operative time was higher by only 10 minutes (not significant) (96).

Laparoscopic Radical Hysterectomy

The term "radical" or "extended" hysterectomy encompasses a variety of different surgeries. Classification is not standardized, and the most widely used ones are not satisfactory, not universal, and not anatomically relevant. A new classification was proposed in 2009, taking into account the lateral extent of excision of the paracervix (type A, midway between the ureter and the cervix; type B at the ureter; type C, at the pelvic sidewall; and type D, with resection of the pelvic sidewall) (113). Two type C subtypes have been defined: C1, with nerve preservation and C2, without nerve preservation. In addition, the radicality of the type B subtype can be extended without impairing the bladder function by adding a lateral paracervical dissection or "parametrial lymphadenectomy" (114). The full laparoscopic hysterectomy will be detailed as the main choice, but options derived from combinations of vaginal and laparoscopic surgery will be mentioned, as they may be useful for subgroups of patients.

Full Laparoscopic Hysterectomy: Technique and Perioperative Outcome

The cul-de-sac presentator is installed as in simple hysterectomy. The upper pedicles are managed as in simple hysterectomy. If the adnexa are preserved, the utero-ovarian vessels are divided 1 cm lateral to the uterine cornua. The peritoneum of the vesical fold is incised and the vesicouterine septum is widely developed. The paravesical space is developed at the time of pelvic lymphadenectomy. The ureters are identified at the pelvic brim and left attached to the lateral pelvic peritoneum. The pararectal space is opened between the ureters and the iliac vessels. The origin of the uterine artery is identified and skeletonized and then controlled using bipolar cautery or a blocking clip (Hem-o-lok) then divided. The superficial uterine vein is cauterized and then divided. The uterine pedicle can then be firmly grasped and elevated, thus opening the tunnel of the ureter. Occasionally, the ureter is attached to the uterine artery by a small ureteric artery that must be carefully

cauterized at a distance from the ureter and then cut. The vesicouterine ligament is then delineated between the vesicouterine space and the ureter; it is stretched by the combined use of the cul-de-sac presentator and of an instrument elevating the bladder. Bipolar cautery can then be safely applied midway between the uterus and the bladder. The bladder base is thus fully separated from the uterus and upper vagina.

The dorsal steps can be achieved before or after the ventral steps. The peritoneum of the posterior leaf of the broad ligaments is incised down to the “uterosacral” fold. The sacrouterine space is found immediately lateral to the uterosacral fold. Once the sacrouterine space is found and developed, the hypogastric nerve and the ureter can be moved medially. The rectouterine ligaments are cauterized and cut at a distance (generally 1 cm) from the uterus. The peritoneum of the pouch of Douglas is then incised and the rectovaginal septum is developed down the posterior vaginal cul-de-sac.

The excision of the paracervix (“cardinal ligament,” “lateral parametrium”) is the next step. The extent of the excision defines the radicality. The dorsal aspect of the cardinal ligament has been made visible after the section of the rectovaginal ligament. The ventral aspect is delineated by opening a narrow space below the ureter (“retrovesical fossa”). The paracervix is then cauterized and divided. It generally contains the deep uterine vein that can be skeletonized and then electively cauterized and transected. The caudal aspect is then freed from the paracolpos from the line of division to the vagina. To achieve this, the paracervix is firmly grasped and elevated. Successive small cauterizations and divisions are made in a horizontal plane until the white structure of the vaginal is visible. The vagina is then divided using the monopolar hook at 1 cm distance from the cervix. The uterus is delivered vaginally. The vaginal cuff is sutured using intraperitoneal suturing techniques. The integrity of the ureter and the hemostasis are checked before closing the trocar sites.

Preoperative Data, Complication Rate, and Postoperative Outcome

Noncomparative data in large series are available, as reported by Spirtos et al. (115) in 2002 on 78 patients. In that series, 94% of the procedures were completed laparoscopically. The mean operative time was 205 minutes, and the mean blood loss was 225 mL. One patient required a blood transfusion. Three patients had unintended cystotomies, 2 patients required laparotomy to control bleeding, and one patient suffered an ureterovaginal fistula. Pomel et al. (116) reported in 2004 on 50 patients. The median operating time was 258 minutes. No conversions to laparotomy were required. Ten patients had early complications (within 2 months of surgery); 3 of them required reoperation. Three patients had late complications (more than 2 months after surgery); 2 of them required reoperation. Three patients experienced recurrence with a median follow-up time of 44 months. A Chinese group (117) reported in 2007 the largest series ever published. Among 317 candidates to laparoscopic radical hysterectomies with lymphadenectomy, 313 procedures were completed laparoscopically. Four patients were converted for bleeding ($n = 2$), colon injury, and hypercapnia. Five cystotomies and 5 vascular injuries were repaired laparoscopically. Postoperative complications occurred in 5% of patients, including five uterovaginal fistulas, one with stenosis of the ureter and 4 with vesicovaginal fistula. In the same year, an Indian group reported on 248 patients with stage IA2-IB1 cervical cancer (118). No patients were converted to laparotomy. Fifteen intraoperative complications were managed laparoscopically and 17 had postoperative complications within 2 months of surgery.

In 2008, Chen et al., in the same team as Xu et al., reported on 295 procedures (119), 290 of which were successful. Para-aortic lymphadenectomy was performed in 156 patients (52.9%), and pelvic lymphadenectomy was performed in all 295 patients.

The median blood loss was 230 mL. The mean operation time was 162 minutes. In 5 cases, conversion to open surgery was necessary due to bleeding (3 cases), bowel injury (one case), and hypercapnia (one case). Other major intraoperative injuries occurred in 12 patients (4.1%). Postoperative complications occurred in 10.8% patients, ureterovaginal fistula in 5 cases, vesicovaginal fistula in 4, ureterostenosis in 3 cases, deep venous thrombosis in 9 cases, lymphocyst in 4 cases, lymphedema in 5 cases, and one case with trocar insertion site metastasis.

In 2009, Pellegrino et al. reported the surgical outcome in a series of 107 patients (120). Conversion to laparotomy was necessary in 6 patients. Median blood loss was 200 mL and median duration of surgery was 305 minutes. Minor intraoperative complications occurred in 2 patients. Five patients needed a second surgery for postoperative complications. In 2010, Lee et al. (121) published a series of 139 patients. Average operation time was 231.1 minutes. Major intraoperative complications included one great vessel injury, one ureteral injury, one colon injury, and 6 cystotomies. In 2011, Yan et al. evaluated the morbidity and oncological outcome in another large series of 240 cervical cancer patients treated with laparoscopic radical hysterectomy and pelvic lymphadenectomy (122). The conversion rate was 1.25%. Intraoperative and postoperative complications occurred in 7% and 9% patients, respectively.

A number of retrospective comparative studies are available. Only series of over 50 patients with laparoscopic radical hysterectomy will be mentioned. In 2004, Jackson et al. reported on 57 women candidates for laparoscopic radical hysterectomy (123). Conversion to laparotomy occurred in 5 cases. A matched control group of radical abdominal hysterectomy was constituted. Statistically significant differences were found: duration of surgery was shorter (median 180 vs. 120 min), blood loss was less (median 350 vs. 875 mL), and hospital stay was less (median 5 days vs. 8 days) in the laparoscopic surgery group. There were no statistically significant differences with regard to nodal yield, completeness of surgical margins or perioperative complication rate. Four major complications (8%, 3 cystotomies and one enterotomy) occurred in the laparoscopic surgery group and three in the open surgery group (6%, one pulmonary embolism, one ureteric injury, and one major hemorrhage). Steed et al. compared 71 patients managed laparoscopically to 205 patients managed by laparotomy (124). No conversion occurred in the laparoscopic group. Blood loss was 300 mL in the laparoscopy group versus 500 mL in the open surgery group. Operative time was longer (3.5 vs. 2.5 h) in the laparoscopy group, in which an increased perioperative complication rate was observed, with 7 cystotomies, one ureteral injury, one bowel injury, and a longer time to normal urine residual. In 2007, Frumovitz et al. (125) compared patients undergoing total laparoscopic radical hysterectomy with patients undergoing total abdominal radical hysterectomy. The mean estimated blood loss was significantly lower in the laparoscopic-surgery group than in the open-surgery group (319 vs. 548 mL). The average operative time was significantly longer with laparoscopic surgery (344 vs. 307 min), but the median hospital stay was significantly shorter (2 vs. 5 days). Infectious morbidity was substantially less frequent (18% vs. 53%) after laparoscopic approach. In 2007, Li et al. reported on a series of 90 laparoscopic radical hysterectomies that were compared to 35 open radical hysterectomies performed during the same period of time (126). Two cases were converted to laparotomy. Consistent with other reports, they found an increased operating time (263 vs. 217 min) for laparoscopic procedures. However, they did not find a reduced blood loss. Interestingly, they investigated the time to recover bowel movements and found a significantly reduced time after laparoscopy (2 vs. 2.4 days). In 2009, Malzoni et al. compared 2 series of laparoscopic ($n = 65$) and open ($n = 62$) radical hysterectomies (127). Consistent with earlier reports, there was less blood loss (55 vs. 145 mL),

median operating time was longer (196 vs. 152 min), and hospital stay was shorter (4 days vs. 7 days) in the laparoscopy group.

The specific question of the extent of parametrial resection and its relationship with urinary complications has been addressed in two studies. Ghezzi et al. (128) compared radical hysterectomy specimens of sequential patients undergoing laparoscopic radical hysterectomies (n = 50) with those of historical controls selected from women who have had conventional open radical hysterectomy (ORH; n = 48). The parametrial width was similar between laparoscopic and abdominal radical hysterectomies. Uccella et al. compared 50 laparoscopic surgeries to 48 patients' historical cohort managed by open surgery. There was no statistically significant difference in intraoperative urinary complications between the groups. Four intraoperative urinary tract injuries in the laparoscopic surgery group (3 cystotomies and 1 ureteral lesions, all repaired laparoscopically) and 2 in the open surgery group (2 cystotomies) occurred. Urinary postoperative complications were: 1 ureterovaginal, 1 vesicovaginal fistula, and 1 delayed ureteric fistula in the laparoscopic group versus none in the open surgery group. In patients without urinary complications, the average width of parametrial tissue removed in the laparoscopy group was 32 mm in patients versus 39.5 mm (129).

Finally, a small-size randomized controlled study is available. The Gateshead group recently evaluated perioperative surgical outcomes and resection size for laparoscopically assisted radical vaginal hysterectomy compared with radical abdominal hysterectomy in early stage IB cervical cancer (128). Fifteen patients were accrued in each group. Statistically significant differences were found between laparoscopic and abdominal approaches, respectively: median duration of bladder catheterization, 4 versus 21 days; average operating time, 180 versus 138 minutes; median blood loss, 400 mL versus 1000 mL, median hospital stay, 5 days versus 7 days; and median opiate requirement in the first 36 hours postoperatively, 30 mg versus 53 mg. All parameters were in favor of laparoscopic surgery. On the other hand, the mean resected lengths were smaller for laparoscopic surgery: mean resected vaginal cuff, 1.26 cm versus 2.16 cm; mean resected cardinal ligament length, 1.30 cm versus 2.79 cm; and mean resected uterosacral ligament length, 1.47 cm versus 4.68 cm. This has to be put in perspective with the trend to reduce radicality in the surgical management of less than 2 cm cervical cancer with negative nodes that are associated with a negligible risk of parametrial involvement.

The technique is thus feasible with a high success rate for a trained gynecologic oncologist with laparoscopic skills, and can be taught by experienced proctors. However, a steep learning curve is observed that prevents widespread use of the technique despite obvious merits. The cut-off is generally set at 45 to 50 cases (131,132). Interestingly, the learning curve has no impact on survival (131), is mainly based on operative time. In 2007, Zakashansky et al. (133) specifically examined the use of total laparoscopic radical hysterectomy in a fellowship program. They demonstrated that greater node counts, decreased hospital stay, and less blood loss are possible without increased morbidity in a training program.

However, provided the necessary efforts to improve skills have been made, excellent results can be achieved. This statement applies to so-called developing countries. The first 50 cases performed in Colombia were as successful as the first 50 cases performed at the M.D. Anderson Cancer Center (134). This adds to the evidence that with adequate teaching and proctorship, and willingness to learn, the technique of laparoscopic radical hysterectomy can be implemented in any place in the world, and all the more in developed countries where the incidence of cervical is still high, and where the additional cost of robotic surgery is not affordable.

Despite the inherent limitations of laparoscopic radical hysterectomy and its associated learning curve, the procedure conveys many documented advantages over the open technique

mainly in terms of blood loss and hospital stay. The outcome balance combining improved quality of life (QOL) without compromising survival is in favor of adopting MIS as the gold standard for radical hysterectomy.

Nerve-sparing Radical Hysterectomy (Type C1)

Nerve-sparing radical hysterectomy has been designed to prevent the frequent urinary dysfunctions associated with classical (type C) radical hysterectomy. Logically, the magnification and lighting provided by the laparoscope has also been used to achieve a precise dissection of the pelvic autonomic nerves.

The technique was pioneered by Possover et al., who identified the middle rectal artery as a landmark separating the neural part from the vascular part of the paracervix (135). The bladder function was significantly less altered after their attempt at preserving the neural part of the paracervix (cardinal ligament).

Since 2010, several investigators reported on full laparoscopic nerve sparing radical hysterectomy (LNSRH). Liang et al. (136) reported on 163 consecutive patients with cervical cancer who underwent laparoscopic radical hysterectomy and pelvic lymphadenectomy, of whom 82 women underwent LNSRH. The average time taken to obtain a post-void residual urine volume of less than 50 mL after removal of the urethral catheter was 7.4 in the LNSRH group compared to 16.75 days. The bladder function recovered to no or minor symptoms in 94% of patients of the LNSRH group compared to 73% for the LRH group. Kavalalis et al. (137) published a series of 32 patients who underwent LNSRH with pelvic lymphadenectomy. The average operating time was 221 minutes. The authors reported that in all patients spontaneous voiding was possible on the third postoperative day with a median residual urine volume <50 mL. Park et al. (138) carried out a retrospective study of consecutive 125 patients with cervical cancer stage IB1 (n = 105) and IB2 (n = 20). In this series, a high rate of urological complications (13/125, 10.4%) was observed. However, these surgical morbidities were corrected with increased experience. Patients were able to self-void at a mean of 10.3 days postoperatively. The return rates to normal voiding function at postoperative 14 and 21 days were 92.0% and 95.2%, respectively. The authors concluded that an LNSRH for stage IB cervical cancer is comparable to the corresponding open procedure in terms of early recovery of bladder function. To summarize, nerve-sparing techniques are feasible laparoscopically.

Type B Radical Hysterectomy with Paracervical Lymph Node Dissection (Type B2)

Paracervical cellulolymphadenectomy consists of removing all the lymph node-bearing tissue located in the vasculonervous web making up the lateral part of the paracervical ligament. The ventral, dorsal, and lateral component of the paracervix are successively cleared. First, the paravesical space is fully developed and the ventral part of the paracervix is exposed; the cellulolymphatic pad ventral to the deep uterine vessels is elevated by blunt dissection, taking care not to injure the vesical, vaginal, and obturator vessels forming the "web." As the anatomy is unpredictable, careful dissection is mandatory. The pararectal space is then opened between the ureter and the internal iliac artery and developed down the level of the sacrospinous muscle, taking care not to injure the hypogastric vessels. The dorsal aspect of the paracervix is exposed. The fatty tissue is less abundant and more fibrous in this area, and must be carefully detached from the vessels of the paracervix. Finally, the lateral part of the paracervix, which is located lateral to the iliac vessels and medial to the obturator muscle, is cleared. The cellular tissue overlying the pudendal vessels and the lumbosacral nerve is visible. It is gently grasped using an atraumatic forceps and bluntly dissected with the tip of a suction cannula.

The technique is designed to offer, in combination with a modified radical hysterectomy (type B), an increased radicality

without additional risk of urinary complications. The concept has been proved in a comparative study of radical hysterectomies with or without paracervical dissection, which concluded that adding a bilateral paracervical lymphadenectomy does not increase the preoperative complications and urinary dysfunctions rates (114).

Laparoscopico-Vaginal Operations

The combination of laparoscopic lymph node dissection and radical vaginal surgery was a major breakthrough in gynecologic oncology. The question is the current place of combined techniques (137). The key issue is training in radical vaginal surgery. Full description of the technique can be found in textbooks (91).

Although the Schauta operation is mastered by only a few gynecologic oncologists, it is of note still the best option in particular patients, such as patients with stage 4 uterine prolapse. The technique involves, after laparoscopic lymphadenectomy, creating and incising the vaginal cuff, opening the pouch of Douglas, opening the paravesical and pararectal spaces, developing the vesicouterine space, and identifying the ureters in the bladder pillar. The uterine arteries are then controlled and the paracervix are then divided under direct vision of the ureters. Type A or B radical hysterectomies, according to tumor extent, are achievable without the perineotomy used by the early pioneers.

Only the laparoscopico-vaginal operations and their results are in the scope of this chapter. Two combinations are available: the Coelio-Schauta procedure – a name designed by Dargent after the French “coelioscopie” (for laparoscopy) – and the Schauthem – a hybrid name designed by Leblanc after the Schauta and Wertheim eponyms. The former name describes a surgery starting laparoscopically and finished vaginally. The latter describes a procedure starting vaginally and finished laparoscopically.

Coelio-Schauta

After the initial description of laparoscopically assisted radical vaginal hysterectomy involving a laparoscopic step (division of the uterine artery and of the superficial uterine vein at its origin) and a vaginal management of the ureters and cardinal ligaments (10–11), several variants of different extent have been described (138).

Large series have been published with reassuring results. Sardi et al. (141) reported on 47 patients who underwent a procedure closer to a classical radical vaginal hysterectomy than a laparoscopically assisted procedure. After 4 years, the overall survival was 100% for stage IA, 88% for stage IB1, and 85% for stage IB2. They suggested that 20 cases were needed to obtain the minimum skill to perform CS. Hertel et al. (142) reported a large series of 200 patients with cervical cancer stages IA to IIIA who underwent a variety of radical hysterectomies, including type III (type C) procedures. A variant including laparoscopic nerve sparing preservation has also been described (140).

Two studies compared the safety, efficacy, and short-term benefits of the Coelio-Schauta (CS) procedure with open Wertheim/Meigs radical abdominal hysterectomy in cervical cancers. Sharma et al. (143) retrospectively analyzed records of 35 consecutive stage IB patients undergoing Coelio-Schauta for early cervical cancer and 32 ORHs. There were statistically significant differences between CS and ORH for duration of surgery (mean 160 vs. 132 min), intraoperative blood loss (479 vs. 715 mL), hospital stay (mean 5 vs. 9.3 days), postoperative complications (6 vs. 20 patients), and duration of bladder catheterization (mean 4.4 vs. 8.8 days). Four CS patients and no open-surgery patients had urinary tract injury. None had long-term sequelae. Their data confirmed that although CS is a suitable alternative to ORH for small-volume stage IB1 cervical cancer with similar clinical efficacy and a superior postoperative recovery and postoperative morbidity profile, urinary tract trauma is a clear risk in the early stages of the learning curve.

Pahisa (142) included 67 patients in the study group. The number of pelvic nodes, disease-free margin, and complications rate were similar in the study and control groups, but blood loss and blood transfusion rates were marginally less in the CS group. Operating time was longer in the first 20 CS patients, but it became comparable to open surgery once the learning curve was completed. Hospital stay was significantly shorter in the CS group and so was the bladder function recovery time. However, no differences were seen regarding long-term urinary and bowel functions between groups. Six percent from the CS group and 13% from the open surgery group had recurrence. Mortality rates were 3% and 9%, respectively.

Schauthem

In 2007, Leblanc described a technique that involved making the vaginal cuff as a first step of the procedure, thus making the laparoscopic step easier (91,145).

In conclusion, radical vaginal hysterectomy combined with laparoscopic lymphadenectomy or laparoscopico-vaginal procedures are still a safe alternative to full laparoscopic radical hysterectomy in the treatment of early stage cervical cancer in selected patients. In clinical practice, the various “minimally invasive” techniques for radical hysterectomy are not concurrent but complementary, and indication of each method is adapted to the individual patient. The full laparoscopic procedure has gained more acceptance.

It must be stressed that familiarity with the radical vaginal hysterectomy technique would facilitate performing specific fertility-sparing radical vaginal trachelectomy in young women with early cervical cancer. Training programs in gynecologic oncology should continue to cultivate radical vaginal surgery training, or alternately selected patients should be referred to a few centers that have kept a sufficient experience in this technique.

Laparoscopic Radical Trachelectomy

Radical trachelectomy is a conservative variant of radical hysterectomy for young patients affected by early invasive cancer on the superficial aspect of the cervix. The first pregnancies were described by Dargent, who used a laparoscopico-vaginal approach allows successful outcomes.

Contrary to radical hysterectomy, the vaginal approach (Dargent operation) remains the gold standard approach for radical trachelectomy. Its oncological and pregnancy outcomes have been extensively documented in large series (146,147,148). As it is essentially a radical vaginal procedure, associated with a laparoscopic lymphadenectomy, a topic that has been addressed above, the Dargent operation is beyond the scope of this chapter and will only be briefly described.

The operation proceeds the same way as the Coelio-Schauta. The first difference is that the uterine artery is preserved. The second and major difference is that the uterus is divided 5 mm below the isthmus. The specimen is sent to the laboratory for assessment of its superior margin by frozen section. The cavity is sounded and a dilator is inserted to widen the canal and facilitate the reconstruction. Once the results of the frozen section determine negative margins, the reconstruction is undertaken. The pouch of Douglas is closed with a running suture. An isthmic cerclage, using the same suture used for the conventional prophylaxis of miscarriage, is then placed. Finally, an isthmovaginal anastomosis is performed using Sturmdorf stitches or interrupted sutures approximating the vaginal mucosa and the isthmic mucosa with great care not to involve the internal os.

Abdominal techniques have been developed, and quickly mimicked by laparoscopic procedures (149) involving a variety of combination of vaginal and laparoscopic steps. The laparoscopic step is generally used for the resection of parametrium. The uterine artery can be preserved. Nerve-sparing techniques

have been described (150,151). The full procedure can be completed laparoscopically, but the surgeon may elect to use a vaginal step that may involve incision of the vagina, retrieval of the specimen, and uterovaginal anastomosis.

In the largest series to date, 27 patients underwent laparoscopic radical trachelectomy (152). The mean operating time was 290 minutes and the mean estimated blood loss was 332 mL. There were no perioperative complications requiring further surgical management. After a median follow-up time of 31 months, there was one recurrence and death from disease. Regular menstruation returned in 24 patients. Six patients attempted to conceive, and three succeeded.

Laparoscopic Pelvic Exenteration

Positive peritoneal cytology, microscopic or macroscopic peritoneal disease, and positive aortic nodes are contraindications to exenteration. As all these conditions can be ruled out using laparoscopic technique, the laparoscope is an ideal tool to assess the feasibility of pelvic exenteration, thus avoiding aborted laparotomies. The issue was addressed for the first time by Plante and Roy (153) and subsequently reported by Köhler et al. (154).

Pomel et al. (1) extended the procedure by actually performing a total laparoscopic pelvic exenteration with a small incision to create an ileal conduit and the diverting ileostomy. The operative time was 9 hours, and the postoperative course was uneventful. The operative technique was then refined to include the making of a continent urostomy through a minimal incision (155). Later, the Toulouse group retrospectively compared patients who underwent laparoscopic pelvic exenteration with open cases from the same period of time (156). In this series, 14 patients underwent laparoscopic pelvic exenteration while 29 patients underwent an open exenterative procedure. Criteria to define a patient as an ideal candidate for laparoscopic approach were: central pelvic tumors of less than 5 cm without pelvic side-wall involvement, body mass index (BMI) inferior to 30, and no need to perform vaginal reconstruction. Operative time, margin status, length of hospital stay, operative and postoperative morbidity, and disease and overall survival were not significantly different between both groups. The benefit of laparoscopic exenteration is then questionable.

Overall, 36 documented cases of laparoscopic pelvic exenteration for gynecological malignancy have been identified in the medical literature (156). The conclusion is that although laparoscopic pelvic exenteration with curative intent is feasible and safe in selected patients, its advantages are not obvious.

A major shortcoming of laparoscopic surgery is the inaccessibility to the full range of techniques to fill the pelvic dead space and reconstruct the vagina. After pelvic exenteration the pelvic space is a main source of postoperative complications, such as pelvic abscess, bowel obstruction, and fistula formation. Filling the pelvic dead space with vascularized tissue, especially with myocutaneous flaps and omental J flaps has contributed to better wound healing, and has dramatically reduced major complications. Pelvic/vaginal reconstruction also restores anatomic appearance, improves body image, and allows sexual intercourse. Vertical rectus abdominis flap (VRAM) is actually the most frequently used, as it is easy to perform, anatomic restoration of the pelvic empty space is very good, and it is associated with a low rate of necrosis and complication rate. Unfortunately, VRAM flap is obviously illogical for patients undergoing laparoscopic PE. Other flaps used for laparoscopic approach are gracilis and gluteal flaps, but both of them require longer operative time and are associated with higher rate of necrosis. Omental J flap covered with skin graft can be used as reconstructive technique. It is the most adapted technique for laparoscopic approach, as it does not require additional incisions. However, pelvic filling is not as good as with VRAM flaps, and long-term results are disappointing.

Therefore, laparoscopic pelvic exenteration is not advisable when patients desire vaginal reconstruction or when there is a large

pelvic defect to cover. Interestingly, the older group of patients is thus more amenable to laparoscopic pelvic exenteration.

Other Procedures

General surgery procedures associated with gynecologic malignancies, such as colostomy or splenectomy for isolated metastasis can be performed laparoscopically or hand-assisted by laparoscopy (157) (see also corresponding section below). Laparoscopy may help the radiation therapist or medical oncologist through the placement of pelvic displacement prosthesis, and guiding the placement of interstitial radiation implants (interstitial brachytherapy implants, placement of intraperitoneal port-a-cath [158]). Laparoscopic ligation of the hypogastric artery has been described as an alternative to embolization in severe hemorrhage related to uterine cancers. We have managed laparoscopically lymphocysts by intraperitoneal marsupialization, and vaginal eviscerations by laparoscopic omentoplasty combined with vaginal closure. New developments may be found using photodynamic detection of implants in follow-up laparoscopies of ovarian cancer patients in apparent complete remission. In an experimental setting, HIPEC (hyperthermic intraperitoneal chemotherapy) has been successfully achieved (159), with interesting pharmacokinetic parameters (160).

A controversial topic in gynecologic oncology is the laparoscopic management of bulky nodes. Freezing such a node laparoscopically is technically possible even in the presence of vascular adhesions. One should, however, consider with caution this dissection because of the hazard of tumor dissemination from nodal rupture. Two options for management are suggested: (a) referring the patient to the radiotherapist after having documented the metastatic involvement by fine-needle aspiration, or (b) opening the abdomen and performing nodal debulking. The senior author feels that limiting to 3-cm nodes, performing an extremely careful dissection with a combination of blunt dissection, sharp dissection, and hydrodissection, and extracting the node via a laparoscopic bag is feasible and safe. Tozzi et al. (161) reported on the debulking of nodes up to 6.9 cm in the aortic or pelvic area in 22 cervical cancer patients. The surgery was successful in 21 patients. One attempt failed as a result of the impossibility to dissect the lumbosacral nerve. One patient experienced postoperative leg palsy and one had chylous ascites. The two complications eventually recovered but the adjuvant treatment was delayed. All women were discharged within 2 days from the operation, except for the two women with complications who remained until day 4. Excluding the two women with complications, adjuvant treatment was started within 7 days postoperatively.

The Case of the Obese Patient

Obesity is a limiting factor for laparoscopic surgery. Visibility is poor, with a short and adipose mesentery, bulky sigmoid colon, and at times inability of the anesthesiologist to adequately ventilate the patient in Trendelenburg position. The surgeon's fatigue is obviously increased compared to nonobese or moderately obese patients. Even if hysterectomy is feasible using the resources of vaginal and laparoscopic techniques, pelvic lymphadenectomy and particularly aortic lymphadenectomy may not be achievable.

While the early reports investigated the feasibility of laparoscopic surgery in obese patients with gynecologic malignancies – there were reservations among surgeons and anesthesiologists at that time of history – several studies soon showed that obesity is an elective specific indication, whenever possible, for the minimally invasive approach. A systematic review has been published by Martinek et al. in 2010 (162). Thirty-nine papers were identified, while only eight met the quality criteria: one randomized trial, two prospective, and 5 retrospective studies. The vast majority of papers report on surgical management of endometrial cancer. The finding is that the conversion rate is in the range of 7.5% to 36% and increases proportionally with

the BMI (163). While former studies suggested that obesity can be the limiting factor when attempting lymph node dissection, more recent reports show similar lymph node counts regardless of BMI in endometrial cancer patients (164).

Laparotomy in the obese patient obviously prolongs hospital stay and increases wound complications. As a result, more morbidity is seen in the open group than in the laparoscopic group. When comparing group of patients managed laparoscopically with a historical group managed by laparotomy, several outcomes are significantly improved: shorter hospital stay, less pain medication, and smaller drop in postoperative hematocrit, at the expense of longer operative time.

In the LAP2 study, conversion rates were 27% in patients with BMI greater than 35 kg/m² and 57% in women with BMI greater than 40 kg/m² (101). The high conversion rate reflects the multicentric design of the study, including less experienced surgeons. In contrast, conversion rate was only 10.6% of 47 obese patients and 7% in 85 with BMI higher than 40 in monocentric series (163,165).

A French study investigated the feasibility of laparoscopic and vaginal surgical approaches in obese patients with endometrial cancer (164). After matching 41 obese patients treated by laparoscopy with 29 obese patients treated by laparotomy, hospital stay was found to be significantly shorter in the laparoscopy group (3.8 vs. 7.4 days), whereas pelvic nodes counts (16.3 vs. 11.5), operative time (149.9 vs. 167.9 min), and disease-free survival (93% vs. 80%) were similar in both groups. One patient treated by laparotomy never received intended radiotherapy because of a delay greater than 3 months caused by cutaneous necrosis.

In a recent series from Louisville (167), 168 women underwent surgery: laparotomy *n* = 103 and laparoscopy *n* = 65, including 12 of them converted to laparotomy. There were 29 patients with BMI over 35 who were managed laparoscopically. Complication rates were significantly lower after laparoscopy compared to laparotomy: overall complications 53.8% versus 73.8 (*p* = 0.01); grade ≥3 complications, 9.2 versus 34.0 (*p* < 0.01); greater than or equal to 3 wound complications, 3.1 versus 22.3 (*p* < 0.01); and greater than or equal to 3 wound infections, 3.1 versus 20.4 (*p* = 0.01).

The limitations mentioned above can be overcome using refinements of laparoscopic technique. Suspension of the sigmoid colon may help. Correct placement of trocars, above the umbilicus, helps to keep a proper distance between the endoscope, the pelvic contents, and the symphysis pubis. Furthermore, the extraperitoneal technique can be used for aortic dissection. The technique overcomes the obstacles mentioned above, as the bowel is not in the way, a Trendelenburg position is not required, and the ergonomics of the surgeon is more acceptable. This approach has been successful in 92% of obese patients in the Mayo Clinic Rochester team (168). In the same mindset of combining available approaches, Benedetti-Panici et al. used a combination of laparoscopy and transverse minilaparotomy, with a success rate of 87% in a series of 39 – none of the conversions in this series was related to obesity (169).

The literature on radical hysterectomy and obesity is scant. Moss et al. (170) reported on the laparoscopic management of 15 patients with early-stage cervical cancer and BMI greater than 30 (up to 56). No case was converted to laparotomy. This group was compared to a group of 43 patients with BMI less than 30. Median duration of surgery, estimated blood loss, median hospital stay, number of retrieved nodes, length of vaginal cuff, and parametrial excision were not affected by obesity.

recurrence, and long-term QOL issues will be addressed, with an emphasis on large series, comparative studies, and randomized controlled studies.

Endometrial Cancer

The mainstay of surgery for endometrial cancer is simple hysterectomy with bilateral salpingo-oophorectomy, along with retroperitoneal staging according to guidelines.

Oncological Outcomes

Six randomized studies comparing oncological outcomes after laparotomy and laparoscopy, respectively, are currently available. The first 5 were included in a meta-analysis published then updated by Palomba et al. in 2009 (171). Only three studies were selected, resulting in a sample of 359 patients (97,124,170). No significant heterogeneity was observed among studies. No significant effect of laparoscopic approach on the disease-free survival, overall survival, and cancer-related survival (OR 0.95, 0.96, 0.91, respectively).

Long-term outcomes of the randomized controlled LAP2 study were published in 2012 (173). The primary study end point was noninferiority of recurrence-free interval. Noninferiority was defined as no more than a 40% increase in the risk of recurrence with laparoscopy compared with laparotomy. Laparoscopy was compared with laparotomy regarding recurrence after surgical management of uterine cancer stage I to IIA. Patients were randomly allocated (2 to 1) to laparoscopy (*n* = 1,696) versus laparotomy (*n* = 920). The estimated hazard ratio for laparoscopy relative to laparotomy was 1.14 (90% confidence interval 0.92–1.46). The actual recurrence rates were substantially lower than anticipated, resulting in an estimated 3-year recurrence rate of 11.4% with laparoscopy and 10.2% with laparotomy. The estimated 5-year overall survival was almost identical in both arms at 89.8%.

In a comparative historical study, Ghezzi et al. (174) presented the outcomes of consecutive patients with clinical stage I endometrial cancer managed laparoscopically with greater than 3-year follow-up (median follow-up of surviving patients, 52 months). Data from 117 consecutive women were compared with a historical cohort of 122 consecutive patients with endometrial cancer who had undergone open surgery. The laparoscopy and laparotomy groups were similar with regard to potentially confounding factors. Similar 3-year recurrence-free survival rates (91.4% vs. 88.5%), as well as similar 3-year overall survival rates (94.0% vs. 93.4%) were observed in the 2 groups.

Quality-of-Life Issues

Patients who undergo laparoscopic surgery seem to report a higher level of satisfaction with laparoscopy when compared to patients treated with total abdominal hysterectomy. They benefit from a shorter recovery time and are able to return to work and full activity more quickly. In a recent prospective, randomized study comparing laparoscopy to laparotomy in the management of endometrial cancer, Zullo et al. (175) prospectively demonstrated that patients treated with laparoscopy did indeed have improved QOL for the first 6 months after surgery.

Quality of life up to 6 months after surgery was also assessed in an RCT comparing total laparoscopic hysterectomy with total abdominal hysterectomy for stage I endometrial cancer (100). A total of 361 participants were enrolled and 332 completed the QOL analysis. Analysis was done according to the intention-to-treat principle. In the early phase of recovery, and up to 6 months after surgery, patients who had laparoscopic surgery reported significantly greater improvement in QOL from baseline, in all subscales apart from emotional and social well-being that are related to patients dealing with cancer.

Surgical Management of Gynecological Malignancies

This section describes oncological issues related to the incorporation of laparoscopic surgery in the management. Survival,

GOG LAP2 also required patients to complete QOL assessments at baseline and then at 1, 3, and 6 weeks, and 6 months postoperatively (176). The first 802 eligible patients randomized in LAP2 participated in the QOL study. Within 6 weeks of surgery, patients assigned to laparoscopy reported significantly better QOL on all scales other than fear of recurrence. In summary, during this 6-week postoperative period, patients assigned to laparoscopy were found to have superior QOL, fewer physical symptoms, less pain and pain-related interference with functioning, better physical functioning and emotional state, earlier resumption of normal activities, earlier return to work, and better body image as compared to those assigned to laparotomy.

The Dutch randomized study also addressed the QOL of endometrial cancer patients having undergone hysterectomy and bilateral salpingo-oophorectomy (95,109). The results of this study are not consistent with others, as laparoscopy patients scored significantly higher only on the physical functioning subscale at 3 months after the procedure. Median quality adjusted life-years (QALYs) were similar in both arms at 3 months.

Reassessment of Incompletely Staged Endometrial Cancers

Occasionally, the diagnosis of endometrial cancer is not established preoperatively. To define the extent of disease, some high-risk patients may benefit from completion staging. Laparoscopy is electively indicated in this setting, to minimize morbidity inherent to a second operation. A faster recovery may also minimize delay of any adjuvant therapy. A recent GOG study of patients with incompletely staged gynecologic malignancies showed that laparoscopic staging was possible in 80% of patients (177).

Cervical cancer

Upfront Radical Hysterectomy

The oncological safety of laparoscopic radical hysterectomy has been questioned. It is now documented in several comparative or noncomparative studies. Follow-up data on the oncologic outcomes have been reported. Spirtos et al. (177) reported on 78 consecutive patients who underwent laparoscopic radical hysterectomy with aortic and pelvic lymphadenectomy. With a mean follow-up of 66.8 months, the estimated 5-year disease-free survival was 89.7% and the estimated 5-year overall survival was 93.6%. Pomel et al. reported a 5-year survival rate of 96% in 50 patients with stages IA2 and IB1 cervical cancers treated with laparoscopic radical hysterectomy (1). Chen et al. (178) reported a 95.2% for IA, 96.2% for IB, 84.5% for IIA, 79.4% for IIB, 66.7% for IIIA, and 60.0% for IIIB overall disease-free survival. The median follow-up was 36.45 months. In 2009, Pellegrino et al. (179) observed a series of 107 patients with IB1 cervical cancer. After a median follow-up of 30 months, 11 patients had a recurrence and survival rate was 95%. Lee et al. (180) reported cumulative 91% and 93% disease-free and overall survival rates, respectively, after a median follow-up of 92.1 months in a group of 139 patients (stage IA $n = 60$, stage IB $n = 76$, stage IIA 3). Yan et al. (181), excluding the lost cases, and including patients with positive nodes, reported in 2011 the outcome of 221 cases after a median 35 months follow-up. The 5-year survival rates for IA2, IB1, IB2, and IIA were 100%, 82%, 66%, and 60%, respectively.

Several groups have compared the oncologic outcomes of laparoscopic radical hysterectomy with those of abdominal radical hysterectomy. After a median follow-up of 49 to 52 months, Jackson (182) did not report a significant difference in recurrence rates or overall survival between the laparoscopic and open surgery group of their trial. Steed et al. (183) found no difference in recurrence rates and similar 2-year recurrence free survival. Li et al. (126) compared 90 patients treated with laparoscopic radical hysterectomy to 35 patients treated with traditional

open surgery. Although the median follow-up was only 26 months, the recurrence rates for the laparoscopic and laparotomy groups were similar. Sobiczewski et al. (185) found a similar 3-year survival in 22 IA-IIA cervical cancer patients managed laparoscopically, compared to 58 patients who underwent laparotomy. However, they observed intraperitoneal recurrence in 2 patients.

The largest comparative study with follow-up has recently been published by Nam et al. (186). A total of 263 patients with stage IA2 to IIA cervical cancer were followed up over 24 months and matched to an equivalent number of patients with comparable prognostic factors. Compared with open surgery, laparoscopic surgery was not associated with a higher risk of recurrence (hazard ratio = 1.28; 95% CI 0.62–2.64) or death (hazard ratio = 1.46; 95% CI 0.62–3.43). Specifically, 16 versus 15/263 had recurrent disease and 12 versus 11 died of disease in the laparoscopy and open surgery groups, respectively. Even in patients with tumors greater than 2 cm in diameter, the risks of recurrence were not higher for laparoscopic radical hysterectomy. Five-year recurrence-free survival rates were 92.8% and 94.4%, respectively ($p = 0.499$).

Selecting Node-Negative Patients with Early Cervical Cancer Most Suitable for Surgery

In many centers, postoperative radiation therapy is routinely given to node-positive patients, thus duplicating the burden of therapy and increasing the complication rate of therapy. There is then a rationale for selecting node-positive patients by performing lymph node dissection first, and proposing radiation therapy only to node-positive patients. In this context, laparoscopy with pelvic lymph node dissection is used as the final workup procedure. In addition, the precaution of excluding node-positive patients is mandatory before proceeding to a radical trachelectomy. Whether the procedure can be limited to the sentinel nodes is still an open question. The reduction of complication rate after sentinel node only versus full pelvic dissection is currently being investigated in a French randomized controlled study.

Surgical Management of Locally Advanced Cervical Cancer

The majority of investigators laparoscopically manage stage IA2 or IB1 patients only. IB2 and II patients are managed by concomitant radiation therapy in most Western institutions. However, the short and long-term outcomes of laparoscopic surgeries for more advanced cases are worth being documented. Yan et al. (181) performed laparoscopic radical surgeries in 34 stage IB2, 35 IIA, and 6 IIB cervical cancers. The number of positive margins was not reported. The 5-year survival rate was 66% and 60% in stage IB2 and IIA, respectively. Hong (187) recently reported on a relatively large series of 34 radical hysterectomies in IB2 cervical cancer patients. The resection margin was free of disease in all patients. Five patients recurred in this group. However, 85% had adjuvant therapy. The rate of long-term radiation induced complications was not reported. It is then still questionable to submit IB2 cervical cancers to upfront laparoscopic surgery rather than concomitant radiation and chemotherapy.

Staging Locally Advanced Cervical Cancer

The surgical staging of locally advanced cervical cancer was initially proposed using laparotomy (transperitoneal or extraperitoneal) and then abandoned as a result of poor cost-effectiveness and major complications. The advent of laparoscopic surgery and the development of extraperitoneal aortic dissection in this indication opened a new era for surgical staging. In addition, an experimental study demonstrated that the adhesion formation rate in the radiation field was minimal after extraperitoneal endosurgical dissection (46). Positron emission tomography/computed tomography (PET-scan) imaging is not sensitive enough to detect metastases less than 5 mm in size (51). There is a significant

proportion of patients with locally advanced cervical who have low-volume metastases and negative PET scans in the aortic area (51,188). The proportion is higher in patients with positive pelvic nodes at PET-scans (22%) as compared with patients with no pelvic node uptake (12%). As a consequence, aortic dissection using the lateral extraperitoneal laparoscopic technique has been adopted by a number of institutions to define the extent of radiation fields (189). In this setting, common iliac dissection is generally added. However, to perform a pelvic dissection or not is still controversial. The therapeutic value of dissection that removes positive nodes and identifies a subgroup of patients likely to benefit from extended field radiation therapy (52), has been suggested but has yet to be demonstrated by a controlled study.

Completion Hysterectomy after Radiation Therapy

The issue of completing definitive radiation therapy by a hysterectomy in locally advanced cervical cancer is controversial. Some patients with incomplete response to radiation therapy with concomitant chemotherapy may benefit from salvage surgery. The extent of such a surgery is adapted to the size and localization of persistent disease. Should the team decide to perform such a surgery, the elective choice is a type A radical hysterectomy, which is potentially associated with less complications. Only one paper addressed the issue of laparoscopic surgery in this context. Colombo et al. (190) retrospectively reviewed 102 patients and were able to compare 46 laparoscopic with 56 abdominal radical hysterectomies after radiation therapy. Seven patients in the laparoscopic group required conversion to laparotomy (15%). Mean estimated blood loss (200 vs. 400 mL) and the median duration of hospital stay (5 vs. 8 days) were significantly lower in the laparoscopic group. Morbidity rates and urinary complications were reduced in the laparoscopic group ($p = 0.04$). Local recurrence rates, disease-free, and overall survival rates were comparable in the 2 groups.

Ovarian Cancer

Reassessment of Apparent Early Ovarian Cancers

On occasion, despite thorough preoperative investigation, patients are operated on for a presumed benign ovarian mass, yet an unexpected diagnosis of ovarian cancer occurs on final pathology, or the operating surgeon does not feel comfortable completing the staging procedure. In such situations, a complete surgical reassessment is required. In presumed stage I disease, the chances of finding more advanced disease in the peritoneum and/or lymph nodes is in the range of 20% to 30%. Laparoscopy may be an excellent alternative to complete the surgical management and staging as contralateral bilateral salpingo-oophorectomy and hysterectomy along with a complete pelvic and paraaortic node sampling, an infracolic omentectomy, and a complete peritoneal assessment may be performed laparoscopically. An extensive review of this indication has recently been published by Iglesias and Ramirez (191).

Over a 10-year experience, Leblanc et al. laparoscopically restaged 42 patients with apparent early ovarian cancer and 7 with fallopian tube cancers (192). Only one patient had to be converted to a laparotomy because of adhesions, and 19% of patients were upstaged as a result of the staging procedure. The authors concluded that laparoscopic surgery meets the standards of a complete staging procedure, spares the patients the inconvenience of a laparotomy, and accurately identifies patients with more advanced disease who require adjuvant chemotherapy.

In a recent GOG trial, Spirtos et al. completed the staging of incompletely staged gynecologic malignancies including ovarian and fallopian tube cancers. They noted a conversion rate of 20% to laparotomy, most often due to the presence of adhesions. Nevertheless, nearly 70% of patients had a successful complete laparoscopic staging and 11% were found to have more advanced disease (193).

In a retrospective review of 20 laparoscopic staging cases and 30 laparotomy staging controls, Chi et al. (194) found no differences between the 2 groups in pelvic or paraaortic lymph node counts and omental specimen size. While there were no complications in the laparoscopy group, there were 3 minor complications in the laparotomy group (2 wound infections and one postoperative ileus). The laparoscopy group had a significantly longer operative time (321 vs. 276 min) but significantly less blood loss (235 vs. 367 mL), and a shorter hospital stay (3.1 vs. 5.8 days).

In a comparative retrospective study comparing 17 patients managed by laparoscopy to 19 patients managed by open surgery, Park et al. (195) confirmed that the number of lymph nodes retrieved and operating time was similar. The laparoscopy group had significantly less estimated blood loss, faster return of bowel movement, and a shorter postoperative hospital stay compared to the laparotomy group. Transfusions were required only in 2 laparotomy patients, and postoperative complications occurred only in 4 laparotomy patients. In contrast with more reassuring data, they observed that 2 patients with stage IA grade 1 and 2 disease in laparoscopy group had recurrence with 1 patient dying of disease.

Although there are no randomized trials comparing both approaches, it appears that a comprehensive laparoscopic of patients with early-stage ovarian cancer is feasible and accurate. The morbidity is lower compared to the same procedure done by laparotomy. However, this procedure should only be performed by experienced and skilled laparoscopists capable of performing advanced and complex oncologic laparoscopic procedures, and with a careful follow-up of patients.

Laparoscopic Surgical Management of Early-Stage Adnexal Cancer

There are uncertainties that are still not well answered with regard to the safety and efficacy of minimally invasive surgery in early-stage ovarian cancer. Until such solid data are available, oncologists should remain very cautious with regard to the use of laparoscopy in the management of suspicious complex adnexal masses and early-stage ovarian cancer. First and foremost, minimal access surgery should not compromise outcome, particularly for patients with early-stage disease who have an excellent prognosis.

This being stated, two series involving a substantial number of patients have been published. Nezhat et al. reported in 2009 a series combining restaging surgeries, surgeries for borderline tumors, and including 25 full laparoscopic management of early ovarian cancers presenting as ovarian masses (196). There were 20 epithelial ovarian tumors and 5 were germ-cell or sex-cord stromal tumors. Only one patient with clear cell carcinoma of the ovary recurred after a mean follow-up of 56 months. A series of 82 cases has been published by Ghezzi et al. in 2012 (197). Although including 17 patients who had reassessment only and were not studied separately, 3-year overall survival and 3-year disease-free survival were 97% and 91.2%, respectively, in the subgroup of 34 patients who had reached or exceeded 3 years' follow-up. No conversion to laparotomy occurred in this series. Thirteen patients (15.8%) experienced postoperative complications. Only one patient had intraoperative hemorrhage requiring blood transfusion. These results are reassuring and confirm the findings of an earlier report (198) in which 2 patients in a series of 24 presented with recurrent disease after a 46-months follow-up.

Laparoscopic Debulking of Advanced Ovarian Cancer

Some investigators have elected to debulk laparoscopically advanced ovarian cancers, mainly after neoadjuvant therapy.

The debulking procedure relies on the electrosurgery or use of devices such as the Argon Beam Coagulator.

Trinh et al. reported in 2004 on 36 patients with chemosensitive (recurrence after 6 months) recurrent ovarian cancer identified on the basis of rising CA-125 (199). About 34 patients underwent successful laparoscopic debulking without requiring laparotomy, 32 had all visible disease resected at laparoscopy and 6% had surgical complications. Median time for surgery was 2.6 hours, median blood loss 70 mL, and median hospital stay 1 day. Seventy-four percent had a complete response after laparoscopic debulking and chemotherapy with a median progression-free survival of 1.1 years. In the same team, Fanning et al. (200) reported on 23 procedures without conversion to laparotomy. Median operative time was 2.3 hours and median blood loss was 340 cc. Median length of stay was 1 day. Six patients (24%) had postoperative complications; none were grades 3–4. They stated that the patients were successfully cytoreduced laparoscopically. However, although all tumors were debulked to less than 2 cm as assessed by laparoscopy, only 36% had no residual disease, which is the current standard of care. Nezhat et al. (201) reported in 2010 on 17 patients who underwent total laparoscopic primary or interval cytoreduction, with 88.2% optimal cytoreduction, as defined by a less than 5-mm disease. Only 2 had a complete cytoreduction. This policy should be thus still considered as investigational.

Surgical Management of Borderline Tumors of the Ovary

Borderline tumors often present as multilocular lesions on sonogram and may have elevated CA-125 levels. Three French and one Italian studies showed that the initial laparoscopic surgery in the management of borderline tumors is associated with a lower rate of complete staging, a higher rate of cyst rupture, and a higher recurrence rate following conservative treatment (202–205). However, despite an incomplete staging, there does not appear to be a detrimental effect on outcome in patients with apparent early borderline tumors (205).

In 2007, a Scandinavian group also retrospectively compared the short-term outcome of 107 patients with borderline tumors (52 serous, 53 mucinous, and 2 endometrioid tumors) operated by laparoscopy ($n = 38$) or laparotomy ($n = 69$), 14 of them being converted from laparoscopy to laparotomy (206). When tumor diameter exceeded 10 cm, intraoperative tumor rupture was significantly more frequent during laparoscopy than during laparotomy. During the 14 to 78 months follow-up time, no relapse occurred in either group. After fertility-sparing surgery, there was no statistically significant difference regarding successful pregnancies between the two groups. The authors concluded that laparoscopic treatment of borderline tumors is feasible in moderate size tumors (<10 cm) and is associated with fewer complications and shorter hospital stay. Laparotomy is still an option in large-size borderline tumors. The cutoff has been set between 5 cm (204) and 10 cm (206).

A majority of papers address only early-stage borderline tumors. The outcomes of 18 patients treated with pure laparoscopic management (treated conservatively in 14 patients) of serous borderline ovarian tumors with peritoneal implants were reviewed by Kane et al. (207). Eight patients relapsed (three with an invasive recurrence), but none of the patients without residual disease at the end of surgery, or invasive implants or disease with a micropapillary pattern relapsed under the form of invasive carcinoma.

The value of a restaging procedure in borderline tumors is controversial since the prognosis of patients with presumed stage I disease is excellent, and the value of adjuvant treatment is questionable even in more advanced disease. In a series of 56 patients referred with a suspected stage IA disease, only 4 (7%) were upstaged (208). Indeed, Darai et al. recently published

their results regarding the laparoscopic restaging of borderline tumors and confirmed the feasibility of that surgical approach. In their series of 42 patients, there were no conversions and no intraoperative or postoperative complications. As expected, they noted that ovarian cystectomies were associated with a higher risk of persistent lesions, and the risk of upstaging was higher in cases of serous borderline tumors (209).

Radical Surgery for Vaginal Cancer

Surgery for the management of cancers of the vagina and/or vulva includes lymph node dissection. For cancers of the upper half of the vagina, the management is similar to that of patients with cervical cancers. Open surgery is the standard, but full laparoscopic surgery or laparoscopically assisted vaginal radical surgery can be used as well. The best indication for laparoscopy may be for the reoperation of patients with incidental cervical cancer discovered at simple hysterectomy. Again, a full laparoscopic surgery, or a radical vaginal procedure assisted by laparoscopy, described as “Schauta *sine utero*” (210), seems to be safe. In this indication, the “Schauthem” procedure may also be used.

PROPHYLACTIC SURGERY

Laparoscopic Bilateral Salpingo-Oophorectomy

Patients at risk of adnexal/peritoneal disease related to a *BRCA* mutation are routinely proposed for risk-reducing surgery consisting of bilateral salpingo-oophorectomy at the age of 40 years or after completion of fertility. It is now widely accepted that the tubes must be removed at the time of oophorectomy, as a number of high-grade serous ovarian cancers are supposed to arise from the lateral part of the tube. As a consequence, removal of the cornual part of the tube is not necessary, as it induces more risks than benefit.

Logically, laparoscopy has become the elective approach. Minimal invasive surgery, which is routinely performed on a day-care basis, is obviously adapted to the concept of prophylactic surgery. The technique is straightforward for any gynecologist. The adnexa is grasped and moved away from the pelvic sidewall. This results in stretching the infundibulopelvic ligament, which can then be individualized, and controlled using bipolar cautery and section, or blocking clips (Hem-o-lok) without any risk of kinking or injuring the adjacent ureter. The peritoneum anterior and posterior to the adnexa is then incised parallel and close to the adnexa. The adnexa are then moved laterally so that its attachments to the cornua are stretched. The tube and the utero-ovarian vessels are then gradually cauterized and cut at a distance from the uterine cornua.

Laparoscopic Radical Fimbriectomy

Young *BRCA*-carrier patients benefit from prophylactic surgery before the age of 50 years. Some of them, particularly those who have not completed their fertility desires, and those who have already experienced breast cancer (and cannot be proposed hormone replacement therapy) may be understandably reluctant to accept early menopause and definitive infertility. In view of the recent literature on ovarian carcinogenesis, Leblanc et al. have recently proposed a novel conceptual surgical procedure they called “radical fimbriectomy” to address the specific issues raised by this particular group of patients (211). Radical fimbriectomy consists of removing the fallopian tube and the fimbrio-ovarian junction, which is the presumed origin of high-grade serous

carcinomas of the fallopian tube, ovary, and peritoneum. The authors hypothesized that this procedure might protect *BRCA* carriers from high-grade serous pelvic carcinoma while preserving their ovarian function until completion of their childbearing desire or the age of natural menopause.

In their seminal paper, they established a surgical technique consisting of removing the tube and the adjacent portion of the ovary. To fully preserve the blood supply to the ovary, care is taken to remove the tube without coagulating the utero-ovarian artery. This is achieved by carefully controlling the tubal vessel after transection of the isthmus. The medial part of the ovary attached to the fallopian tube by the tubo-ovarian ligament is then excised. Approximately one-quarter of the ovary is removed. Care is taken to preserve the infundibulopelvic blood supply to the uterus. To achieve this step of the operation, efficient hemostasis, minimal trauma to the remaining ovary, and preservation of the specimen for pathological examination are required. The authors compared four methods of partial ovarian transection: sharp division, stapler, bipolar division, and harmonic scalpel. Fourteen women were enrolled in a pilot study. They underwent radical fimbriectomy, and after assessment of hemostasis, had definitive oophorectomy in the same operating session. Sharp and EndoGIA appeared to be the safest methods of ovarian resection providing the best specimen quality for pathological examination.

The benefit of approach in terms of fertility and prevention of ovarian cancer is still hypothetical and is currently assessed in a prospective study in France. Although it does not prevent type 1 ovarian cancer, it might be preferable to no prophylactic surgery at all, as it prevents fallopian tube cancer or ovarian cancer precursor, and may prevent type 2 ovarian cancer, which is the most frequent histologic subtype observed in *BRCA* carriers. Indeed, Leblanc et al. found p53 signature and/or overexpression of KI 67 in four tubes or inner part of the ovary. No cancer precursor was identified in the remaining part of the ovaries.

If the proof of concept is obtained in the future, laparoscopic radical fimbriectomy may benefit a subset of *BRCA* carrier patients. Women who undergo radical fimbriectomy should continue to receive regular multimodal evaluation and be advised of the risks involved until they finally accept secondary oophorectomy after completion of fertility desire or after the age of 40.

Laparoscopic Ovarian/Adnexal Preservation

Discussion about the indication for ovarian preservation at the time of radical hysterectomy for cervical cancer is beyond the scope of this chapter. From a technical point of view, laparoscopic ovarian preservation is straightforward. Bipolar cautery followed by section, or more sophisticated instruments ensuring preventive hemostasis and section, is used to gradually separate the adnexa from the uterus. It is advised not to divide too close to the uterus, as the vascular supply is more easily controlled stepwise at a 1-cm distance from the uterus. The round ligament is divided first. The isthmus of the fallopian tube and the internal tubal artery are coagulated and divided. A firm divergent traction of the uterus and the adnexa stretches the area of the utero-ovarian vessels and the utero-ovarian ligament. These structures are gradually cauterized and cut. The ovaries are left in place in the pelvis or alternately can be transposed if a postoperative radiation therapy in young women is expected.

The main indication for ovarian or adnexal transposition is the case of young patients undergoing pelvic radiation therapy for malignant disease such as lymphoma, pelvic sarcoma, or rectal cancer. In this context, ovarian transposition is the preferred option to keep functional tubes. Laparoscopy is the logical approach in this indication. It results in shorter recovery and reduced adhesion formation rate, which is especially important in patients when radiation therapy is to be given. In gynecologic

oncology, ovarian transposition has been proposed in patients with cervical or vaginal cancer managed by preoperative brachytherapy. In this context, before definitive radiation therapy or postradiation hysterectomy, adnexal transposition is more likely to preserve the ovarian vascular supply. Again, laparoscopy is the preferred approach for the same reasons.

The benefit of prevention of estrogen deficiency is minimal considering: (a) the availability in gynecologic cancer patients of hormone replacement therapy, (b) the risk of ovarian failure immediately after transposition, and (c) the frequency of early menopause when the ovaries are transposed. On the other hand, the psychological benefit of retaining normal ovaries and a normal hormonal cycle is not to be neglected. The preserved ovaries are available for assisted reproductive technologies followed by surrogate pregnancy. However, the benefit decreases with age. The age of 40 is generally considered as the upper age limit for ovarian transposition. The risks are represented by the high incidence of ovarian cysts and by the risk of ovarian metastasis from cervical cancer. An estimate of the risk is available in a large study by Shimada et al. (212). The incidence of ovarian metastasis in patients with cervical cancer was 0.22% for stage IB, 0.75% for stage IIA, 2.17% for stage IIB with squamous cell carcinoma, and 3.72%, 5.26%, and 9.85%, respectively, in adenocarcinoma. Ovarian metastasis occurred more frequently among patients with adenocarcinoma than among those with squamous cell carcinoma (5.31% vs. 0.79%). Outcome for patients with ovarian metastasis was poor. In that study, the presence of ovarian metastasis did not correlate with lymph node involvement or parametrial invasion, in contrast with earlier studies. Ovarian preservation is thus safe in young patients presenting with early squamous cell carcinoma of the cervix. It can be proposed at the time of a staging laparoscopy for sentinel node procedure or staging lymph node dissection (213).

The technique of adnexal transposition is based on several principles. (a) The adnexa is detached from the cornua and left with the infundibulopelvic vascular supply. Kinking or torsion of the adnexal pedicle must be avoided to preserve the vascular supply. (b) The ovaries must be placed intraperitoneally as high, anterior, and lateral as possible to reduce exposure to radiation therapy. In this regard, placing radiopaque clips on the most caudal aspect of the transposed ovaries is of help to estimate the dose of radiation therapy received by the ovaries. (c) The high positioning of the adnexa must be secured with a minimum of direct trauma to the ovary by suturing or manipulation, using the tube to anchor the adnexa. Staples, tackers, or blocking clips can be used to attach the fallopian tube to the peritoneum. The pedicle can be left in the peritoneal cavity after division of the peritoneum of the paracolic gutter. It may be preferable not to incise the peritoneum, and rather create a peritoneal tunnel between the pelvis and a peritoneal opening created at the appropriate location. The adnexa is pushed in the tunnel and retrieved in the peritoneal cavity through the high opening. The technique has the advantage of further maintaining the high position of the adnexa, and avoiding the risk of bowel obstruction secondary to an incarceration of a bowel loop below the adnexal pedicle. However, the success rate of the procedure may be as low as 65% (214). Incidentally, the successful laparoscopic management of a metastatic adenocarcinoma arising on a transposed ovary has been reported (215).

NEW TECHNIQUES IN MINIMAL INVASIVE SURGERY

Some limitations of laparoscopic surgery are overcome by the development of new techniques. The case of the big mass may be managed using the hand-assisted laparoscopy (HAL). The limitations due to surgeon's fatigue or the difficulties of laparoscopic training are addressed by the development of robotic-assisted

laparoscopic surgery (RALS). A number of investigators are pushing the envelope and are investigating a further reduction of trocar incision, in size (microlaparoscopy), or in number (single-port), or using natural orifices transluminal endoscopic surgery (NOTES).

Hand-Assisted Laparoscopy

Hand-assisted laparoscopy (HAL) has been introduced as an adjunct to conventional laparoscopic surgery to facilitate the surgery and reduce the rate of conversion to laparotomy. It is used more frequently by gastrointestinal (GI) and genitourinary (GU) surgeons, and procedures such as splenectomy, pancreatectomy, hepatectomy, nephrectomy, prostatectomy, aortofemoral bypass, and colectomy have been successfully performed by HAL. The HAL approach implies a 6- to 8-cm skin incision to place the gel port through which the surgeon's hand and the laparoscopic instruments can be introduced while maintaining the pneumoperitoneum. HAL confers several advantages over laparoscopy alone: return of tactile sensation, improved spatial relationships, rapid exploration of the abdomen, palpation of intra-abdominal organs and masses, retraction and reflection of tissue planes, atraumatic blunt dissection, rapid control of bleeding, and lysing of dense adhesions. Even though a longer incision has to be made, HAL appears to maintain all the benefits of conventional laparoscopic surgery, that is, less postoperative ileus and pain, less blood loss, and shorter hospital stay. In addition, HAL frequently reduces the operating time and shortens the learning curve.

Only a few groups have reported their experience so far in gynecologic oncology surgery. Spannuth et al. reported their experience with the management of 29 patients with a pelvic mass by HAL versus 41 managed by conventional laparotomy. The two groups were comparable in terms of age, BMI, and size of the mass, and they found that HAL was associated with statistically lower blood loss, shorter hospital stay, and fewer postoperative complications (216). Krivak et al. approached 25 patients with ovarian cancer by HAL; 88% of the cases were successfully completed by HAL (217). HAL has also been used to manage recurrent disease. The ideal situation is one where the recurrence appears to be an isolated mass. Chi et al. described the technique for HAL splenectomy in 5 patients with an isolated recurrence in the spleen. The procedure was safely performed without complications (218).

The reason why HAL has not spread in gynecologic oncology is probably the competition with a simple and less expensive approach, which is the combination of laparoscopy and minilaparotomy. In an RCT, Benedetti-Panici et al. addressed the efficacy in terms of intraperitoneal spillage of laparoscopically guided minilaparotomy (LGM) compared with operative laparoscopy for large adnexal cysts (219). Sixty eligible patients affected by adnexal cysts with diameter between 7 cm and 18 cm were randomly assigned to either operative laparoscopy or LGM. In the per-protocol analysis, spillage occurred in 87% of the laparoscopy patients versus 29% in the minilaparotomy group. In an intention-to-treat analysis, operative times were significantly shorter in patients who underwent LGM (48 vs. 85 minutes). Surgical difficulty was significantly higher in patients treated with laparoscopy. However, postoperative stay was shorter (1 day vs. 1.5 days).

The combination of laparoscopy and midline minilaparotomy is thus a practical approach for the management of large ovarian cysts. Considering the need for a comprehensive assessment of the peritoneal cavity, minilaparotomy by itself is not acceptable. Considering the risk of spillage attached to laparoscopy, minilaparotomy is the logical complement to laparoscopic exploration of the abdominal cavity. Minilaparotomy for the decompression of the cyst without spillage, laparoscopy, or diagnostic laparoscopy

followed by a focused minilaparotomy can be chosen depending on the presentation.

Benedetti-Panici et al. recently assessed the role of LGM using a transverse incision in morbidly obese patients (169). There were 39 patients with BMI equal to or over 40 who underwent a variety of gynecologic surgical procedures including surgical management of early endometrial cancer. LGM was feasible in 34 patients. Peritoneal malignancy was found in two patients. In three patients, conversion to laparotomy was necessary due to adhesions, parametrial involvement, and vascular injury, respectively. The use of transverse minilaparotomy is logical in obese patients with early uterine malignancy. In contrast, primary laparoscopy avoids inadapted transverse incision in patients with peritoneal spread.

Microlaparoscopy

Further decrease of invasiveness of the conventional laparoscopic approach may derive from the reduction of trocar incision. Whether such an effort is relevant or not in gynecologic oncology is another question. As microlaparoscopy has been shown to be associated with reduced analgesic need in benign surgery, any technique aimed at improving patient outcome deserves consideration.

Ghezzi et al. recently presented an initial experience with microlaparoscopy in the surgical treatment of endometrial cancer and compared its outcomes with those of conventional laparoscopic approach (220). About 23 patients underwent surgical staging of endometrial cancer using exclusively 3-mm working ports and a 3- or 5-mm laparoscope at the umbilicus. Historical controls selected from consecutive women who have had staging with conventional laparoscopy ($n = 80$). Conversion from microlaparoscopy to a conventional laparoscopic technique occurred in 2 cases (9.7%), while there was no conversion to open surgical staging in either group. There were no significant differences between the microlaparoscopy group and the control group with regard to estimated blood loss, number of pelvic lymph nodes (average 19.2 vs. 18.6), and complication rate (intraoperative: 0% vs. 2.5%, postoperative: 8.7% vs. 13.7%). Operative time was similar between the two. The median length of hospital stay was 2 (1–10) days for women undergoing microlaparoscopic procedures compared to 3 (1–15) days for those undergoing conventional laparoscopy ($p = 0.001$). However, the same group did not find any benefit in terms of postoperative pain after microlaparoscopic hysterectomy compared to laparoscopic hysterectomy (221).

Single-Port Laparoscopic Surgery

The single-port approach represents the logical development of multiport laparoscopy toward less invasive procedures. Although the transumbilical approach is the most generally used, the extraperitoneal approach is being developed especially for paraaortic node dissections.

Instrumentation

A single incision of 2 to 3 cm seems enough to introduce the single port device. Different systems are available. The first attempts of single port surgery use a wound retractor on which was fixed a surgical glove. Instruments and optique were passed and secured through the extremities of the glove fingers. The TriPort (Olympus) has a dedicated endoscope with a curved handle to facilitate the use of the regular straight instruments. All the stuff is passed through a specifically designed port with trocars. The SILS system (Covidien) provides a small rubber doughnut that accommodates dedicated or regular 5- to 10-mm trocars for a regular 10-mm optique, and two to three conventional 5- to

10-mm laparoscopic instruments. Recently, curvable instruments are available. The Gelpoint system (Applied) offers a specific 8-cm protected ring (Alexi) on which is fixed a 10 cm Gelpoint. This port is made of jelly through which four dedicated 5- to 10-mm ports are passed for the regular optique and instruments (222). One experimental study compared the 3 systems and did not observe any significant difference (223). The choice of the technology is only the effect of surgeon's preference. The advantage of the Gelpoint system is the possibility to extract specimen through the port-site or the jelly with no need of bags since the orifice is protected by the wound retractor ring.

Current Experience in Gynecologic Oncology

Single-port laparoscopic surgery (SPLS) has been attempted first to perform simple procedures such as adnexectomy or hysterectomy for endometrial cancer. So far, results do not show any increase in complication rate and patients seem to be satisfied with the cosmetic results. Recently pelvic and paraaortic node dissections were reported through SPLS. Escobar et al. published the first results using a transumbilical approach (224), while Gouy et al. reported their initial experience using the extraperitoneal approach (225). Results of these preliminary reports show that this approach is feasible and reproducible with no apparent increase in morbidity. However, the initial experience is challenging and advantages are not clear and warrant further investigation. A first single institution compared SPLS using the SILS system and laparoscopy and the Gelpoint system combined with the Da Vinci robot. It showed that surgery through a unique site was feasible and reduced the need of postoperative analgesics in patients. Recent development may come from the use of single port technology in robotics to perform a single-port robotic surgery (SPRS). Current experiments in animals and cadavers seem satisfactory and attractive for the human transfer of this technology (224,226).

Advantages and Shortcomings of LPLS

A multi-institutional retrospective comparative study compared SPLS to conventional multiport laparoscopy or robotics for the management of early endometrial carcinomas. Three groups of 30 patients operated with one of each method were pair-matched according to age, BMI, and pathological characteristics of the tumor. Finally, results did not significantly differ between the three methods in terms of operative time, complication rates, node counts, or length of stay (227). Another possible advantage of SPLS is the possible reduction in postoperative pain level or pain killer consumption. However, so far, results did not show a clear advantage over traditional laparoscopy. Finally, cosmetic satisfaction seems the only objective advantage of SPLS.

In contrast, SPLS needs a clear learning curve necessary to overcome the drawbacks of this approach. Paek claimed that 40 cases were necessary to master single-port total laparoscopic hysterectomy (228). A steep Trendelenburg positioning is necessary to permanently clear the pelvis from bowel loops. A good coordination with the video assistant is necessary to avoid "knitting" between the instruments and optique. Another problem due to reduced triangulation is the difficulty to see the tips of the regular laparoscopic instruments, which may result in injuries, especially if cutting, monopolar cautery, or ultrasound is activated. The advent of an efficient 3D vision and the development of articulated instruments are eagerly awaited. However, a good experience in conventional laparoscopy is necessary before engaging in complex radical procedures. Despite these limitations, Yim et al. showed improved short-term outcome, albeit in a retrospective study, with reduced blood loss, shorter hospital stay, earlier diet intake, and reduced postoperative pain, when 52 patients following single-port hysterectomy were compared to 157 patients who underwent conventional total laparoscopic hysterectomy (229).

Variants

A variant of single port surgery is the use of flexible endoscopes. In the Toulouse Cancer Center group, flexible endoscopy has been investigated as a tool to explore remote areas of the peritoneal cavity. In an experimental study in cadavers, flexible endoscope was compared to 0° and 30° rigid endoscopes. Diaphragmatic areas explored with the flexible endoscope are significantly larger than with the other techniques. On average, 135 (range, 66–225), 168 (range 96–306), and 201 (range, 128–399) cm² were observed using 0°, 30°, and flexible laparoscopes, respectively. *P* values deriving from exact Wilcoxon test for paired data was 0.0019 between 0° and 30° endoscopes and between 30° and flexible endoscopes. The 30° endoscopes were consistently better than 0° endoscopes for the observation of the underface of the diaphragm and the spleen (230).

Natural Orifice Transluminal Endoscopic Surgery (NOTES)

Natural orifice transluminal endoscopic surgery has recently emerged as a new frontier resulting in endoscopic surgery without visible and painful scars. NOTES uses natural orifices as port of entry. Although in some regards the single port transumbilical laparoscopy may be defined as a natural orifice surgery, we will address in this section only the accesses involving no skin scar, mainly the vaginal route in female patients.

NOTES has mainly been developed in general surgery. The most common procedures are cholecystectomy, appendicectomy, and peritoneoscopy mainly performed via transvaginal access. Applications in clinical practice and the evidence base for each application were recently reviewed (231). An electronic literature search was performed. There were no randomized controlled studies in the literature on the date of review. The strongest evidence came in the form of large, multicenter trials with 300 to 500 patients. However, the vast majority of NOTES procedures worldwide are performed in a hybrid fashion with a variable amount of laparoscopy. The results are encouraging, comparable with gold standard techniques on morbidity and mortality when the transvaginal route is used. Short-term operative outcomes were also similar when compared to the gold standard techniques. However, morbidity appears to be higher when the transgastric route is used.

To our knowledge, no clinical application in gynecologic oncology has been described in the literature. The feasibility of SLN biopsy using NOTES has been assessed in an animal model. In 10 female pigs, the endoscope was introduced through a right lateral colpotomy. Internal iliac vessels were visualized followed by the identification of external iliac vessels. The aorta and vena cava were visualized. All but one sentinel nodes were identified by NOTES procedure. No major complication was observed in this series. A total of 19 SLN were harvested, of which 11 were from the left side and 8 from the right side. Fifteen lymph nodes were obtained from the iliac vessels or the promontory and 4 from the lateral aortic or preaortic region (232).

In another innovative investigation, Nassif et al. assessed the feasibility of extraperitoneal lymphadenectomy using NOTES in a porcine model (233). Using a transvaginal access to the retroperitoneum, they successfully performed 3 pelvic lymph node excision and 3 others in the laterocaval, intraaorticocaval, and lateroaortic regions. All animals survived. One accidental peritoneal perforation, 1 diffuse anterior abdominal wall emphysema, 1 abdominal wall bleeding secondary to electrical muscle stimulation, and 2 pneumoperitoneums evacuated by Veress needle insertion were experienced.

In conclusion, experimental studies suggest in the future that NOTES may be a potential alternative to reduce morbidity during staging procedures for gynecologic malignancies. Prospective pilot randomized series are necessary to establish the safety and

the real benefits of this new technique. The absence of any visible scar (“the memory of the operation”), and the reduction in postoperative pain (still to be demonstrated) must be balanced, as for SPLS, with significant technical difficulties related to the method: first is the risk of intra-abdominal infection and spillage by the opening of a hollow viscus (that needs to be securely closed at the end of the procedure by a clip or a suture) and the difficulty to sterilize flexible endoscopes and operative channels. Control of the gas pressure through endoscope is another difficulty and a technologic challenge. Then the absence of tactile sensation due to the length of the endoscope and flexible instruments, not compensated by a stereoscopic vision (as in robotics), the disorientation due to the use of a flexible endoscope, which should be compensated in the future by a navigation system using either augmented or virtual reality. A dissection through a colpotomy may be questionable from an oncological point of view. Finally, the sexual outcomes of this vaginal scar should be assessed. However, in spite of these current drawbacks, NOTES is an attractive approach, still in development, that deserves to be watched, especially when it will be possible to couple dedicated instruments to a robot.

Computer-Assisted (robotic) Surgery

Prepared in collaboration with Arie Reiss, MD

With the advent of laparoscopy, the concept of MIS developed, reaching challenging levels in the more complex surgeries performed by very skilled gynecologic oncologists. Limited by straight rigid sticks allowing 5° of freedom in a counter-intuitive hand-eye coordination environment, with an often unsteady two-dimensional image, the technology has remained a challenge to master for most clinicians, with a long learning curve, leading to low implementation in complex oncologic surgery. Although the landmark LAP-2 study, a randomized study comparing between laparoscopy and laparotomy for endometrial cancer, clearly established the benefits of minimal invasive approach (101); implementation has not followed, with most patients not benefitting from the MIS approach (234).

The drive of the military and NASA to develop tele-surgery has ultimately led the FDA to approve a civil computer-assisted surgical system, a “robot,” the da Vinci Surgical System, by Intuitive Surgical (Sunnyvale, CA) in July of 1997. Computer assistance, an integral and crucial part of the robotic platform, enhances dexterity as a result of improved articulation, scaled tremor-free motion, and true stereoscopic immersion vision with improved ergonomics. The development of the robotic platform is reflected by the increasing number of publications, most using the da Vinci robots, the only approved robotic platform at the present time.

As with every new line of thought or technology, robot-assisted surgery has met a lot of resistance, often with excellent argumentation (235). In a nutshell, critics of computer-assisted (robotic) MIS claim that it is associated with high capital and operating costs and with longer overall operating room times. To assess the value of this new platform, a systematic evaluation of clinical effectiveness and economic analysis is presented.

Robotics as a Tool to Increase the Patient Population Benefitting from MIS

The technical advantages offered by the robotic platform allows for the use of maneuvers similar to open procedures, with the added value of magnified immersion images. The robotic platform has thus helped overcome many of the limitations of traditional laparoscopy, enabling more gynecologic oncologists to feel comfortable and perform more complex cases via MIS, which ultimately allows more patients to benefit from the advantages of MIS. In many centers the introduction of robotics has drastically changed the surgical approach and increased the proportion of

Table 10.1 Theoretical Considerations for Robotic-Assisted Surgery in Gynecologic Oncology

Advantages	Disadvantages and Concerns
Intuitive operation Increased dexterity Improved vision Faster adoption Availability of MIS to most patients.	Short-term outcome: lack of level I evidence. Long-term oncologic outcome: no data presently available Increased operative time compared to open surgery.
Reduced Complication rates Pain Bleeding, transfusion rate Length of hospital stay compared to open surgery. Conversion rate compared to laparoscopy.	Cost Upfront high cost of system Significant maintenance cost Instruments cost.
Lymph node yield comparable to laparoscopy and increased compared to laparotomy	Access to more than one quadrant challenging Robot size Lack of haptics (force feedback) Removal of large uteri intact through the vagina may be challenging.

MIS, minimal invasive surgery.

patients benefitting from MIS. In one of the most extreme cases, the rate of patients with endometrial cancers, uterine sarcomas, and cancers of the cervix treated by MIS increased within 2 years from the introduction of the surgical robot from 17% to 98% (236), and a similar evolution was reported by others (237,238). Two populations of patients with a high surgical risk due to comorbidities, the elderly, and obese, had a high conversion rate in the laparoscopic arm of the LAP-2 study (101). In the following paragraphs, data are presented that indicate that this new platform is associated with a neutralization or reversal of the risk factors associated with poor outcome following MIS in obese and elderly patients, allowing these women to benefit equally, if not more, from MIS.

Obese Patients

The prevalence of obesity in North America has increased steadily and is now considered endemic, with significant health implications (239). Currently 2 out of 3 U.S. adults are estimated to be overweight or obese (239). For this reason, it is imperative to determine the most efficacious surgical approach for this patient population that is at risk of significant morbidities from open surgery both intra- and postoperatively (240). MIS has clearly shown benefits for obese patients, but its general application in the obese and morbidly obese populations remains poor in large part due to surgeons' perceived and practical difficulties in completing the procedure laparoscopically (241). In the largest prospective randomized trial comparing laparoscopy with laparotomy for the surgical staging of uterine cancer, GOG LAP2, patients with a BMI of greater than 35 kg/m² were initially ineligible for the study (101). Subsequently in the final analysis of LAP2, BMI was identified as a risk factor for conversion to laparotomy with a rate of conversion of 26.5% in patients with BMI of 34 to 35 kg/m², and 57.1% in patients with BMI greater than 40 kg/m². Gehrig et al. retrospectively compared 49 obese or morbidly obese patients who underwent robotic surgery with a similar historical cohort undergoing laparoscopic surgery for endometrial cancer (242). Robotic surgery resulted in shorter operative times, less blood loss, increased lymph node yield, and shorter hospital stays (242).

Seamon et al. at Ohio State University compared robotic surgery and open surgery in obese patients with endometrial cancer and demonstrated that robotic procedures were associated with a reduced transfusion rate and fewer complications, be it wound or other complications (243). Robotic-assisted MIS was shown to be not only feasible, but also appeared to neutralize the risk factors for surgery associated with obesity. In the report by Lau et al. obese patients had the same clinical outcome with similar perioperative experiences, and low conversion rates (5.6%), compared with nonobese women. The conversions were all at the end of the procedure only to remove enlarged uteri that could not be delivered intact via the vagina (244). These authors then adopted side docking and in patients with enlarged uteri, bisected the specimens within large endobags introduced via the vagina at the end of procedure, with a decrease of conversions to below 1% (244). Overall, in light of the reduced morbidity and high patient satisfaction, robotic surgery appears superior for obese women, and should be considered when counseling these patients with gynecologic cancers for surgery (243,244,245,246).

Applications of Robotic Surgery in Gynecologic Malignancies

Cancer of the Cervix

Robotic Radical Hysterectomy

Radical hysterectomy is a complex surgery with well established potential complications. The average blood loss during laparotomy is around 500 mL. Loss of bladder sensation and lymphocyst formation were each reported in about 5% to 15% of cases, and urinary tract injuries occur in 1% to 2.5% of cases. More severe complications, such as urinary fistulas or rectal injury, occur in up to 5% of patients.

In spite of the reports of the advantages of the laparoscopic over the open approach, laparoscopic radical hysterectomy has scarcely been adopted in surgical practice, remaining in the hands of a few highly skilled surgeons, due to the inherent complexity and difficulty of the technique.

With the advent of the robotic platform, several programs that did not offer MIS for patients with cancers of the cervix in view of the perceived complexity of the laparoscopic approach for radical hysterectomy, shifted uneventfully to robotic surgery, allowing more patients to benefit from the minimal invasive approach (247,248,249). Similar to laparoscopy, the MIS approach using the robotic platform was associated with reduced blood loss and transfusion rates, fewer complications, and significantly shorter postoperative length of stay when compared to radical hysterectomy by laparotomy (Table 10.2).

The currently published studies, although limited by small group sizes and short follow-up periods, support equivalent oncologic outcome with laparotomy, laparoscopic, or robotic radical hysterectomy. Nezhat et al. compared radical hysterectomy following robotic surgery (13 patients, median follow-up 12 months) and laparoscopic approach (31 historical patients, median follow-up 29 months) (250). There were no recurrences in either group. Magrina et al. followed 27 patients after robotic radical hysterectomy for early cervical cancer (251). At a mean follow-up length of 31 months (range, 12–51), no patient had experienced recurrence. Cantrell et al. retrospectively assessed the progression-free survival and overall survival for 63 women with cervical cancer who underwent type III robotic radical hysterectomy (249). Median follow-up was 12.2 months (range, 0.2–36 months). The comparison was made to a similar historical group of ORHs. There was no statistically significant difference in progression-free survival (94% vs. 89%, $p = 0.27$) or overall survival at 36 months (94% vs. 93%, $p = 0.47$).

Overall, early evidence suggests that robotic radical hysterectomy may be a valid alternative to open radical hysterectomies,

with superior short-term results and similar oncologic outcomes (Table 10.2). A prospective randomized trial comparing minimally invasive radical hysterectomy (laparoscopic or robotic) with laparotomy is currently underway (252).

Robotic Radical Parametrectomy

Only 2 studies presently report on small series of patients following radical parametrectomy performed using the robot. Ramirez and colleagues reported on 5 cases with squamous cell carcinoma of the cervix (253). None of the patients needed adjuvant treatment following the radical parametrectomy. One patient had an intraoperative cystotomy, and a second patient presented with a vesicovaginal fistula and a lymphocyst. During the short follow-up reported (mean, 7.5 months; range, 1.4–13.8) no recurrences were observed. Vitobello and colleagues recently reported on 11 cases, 5 with squamous cell carcinoma of the cervix, 2 with adenocarcinoma of the cervix, and 4 with a recurrence of endometrial carcinoma (254). One intraoperative cystotomy occurred and one patient suffered an intra-abdominal hemorrhage 15 days after surgery. Three patients required adjuvant treatment. In a median follow-up period of 19 months (8–36), one patient experienced a recurrence. These results are comparable to the reported results of open and laparoscopic radical parametrectomy (255–257). The authors of both robotic reports concluded that this procedure is feasible and can be performed with an acceptable complication rate.

Robotic Radical Trachelectomy

In view of the small number of surgeons mastering the advanced vaginal surgical skills required for performing Dargent's, or the laparoscopic skills required for performing laparoscopic radical trachelectomy, robotic surgery might offer an attractive alternative (258). Nick and colleagues (259) recently compared a series of 12 cases of radical robotic trachelectomy with 25 cases of open radical trachelectomy. Robotic radical trachelectomy was associated with significantly less bleeding and shorter hospital stay. Operative time, rate of serious complications, and histopathologic results were comparable. Four patients of the robotic group required conversion to hysterectomy due to close margins (<5 mm) found on the intraoperative frozen section biopsy. The rate of hysterectomy was significantly higher than in the patients who underwent open surgery.

Endometrial Cancer

In the last 20 years a considerable amount of data supporting the use of laparoscopy rather than laparotomy in the treatment of endometrial cancer were presented, culminating in the LAP2 trial, a large randomized phase III trial performed by the American Gynecologic Oncology Group (101). Despite this compelling evidence, the adoption of laparoscopic surgery for endometrial cancer staging was slow and only a minority of the patients benefitted from its advantages. In a survey taken among members of the Society of Gynecologic Oncologists in 2005, only 8% of responders performed more than 50% of their endometrial cancer staging procedures laparoscopically (234).

Since the approval of the DaVinci surgical system for use in gynecologic surgery in 2005, endometrial cancer has been the most widespread indication for robotic surgery in gynecologic oncology. Several investigators have reported on their experience with the use of the DaVinci system for surgical staging of endometrial cancer (Table 10.3), and compared their results to historic cohorts treated either by laparotomy or laparoscopy. The results were grouped in 2 meta-analyses (260,261) that were published in 2010 (Table 10.3). The results of these meta-analyses are slightly different due to different inclusion criteria.

Overall, in both meta-analyses, when robotic-assisted staging surgery was compared to conventional laparoscopy (Table 10.3), no differences were found in operation time, lymph node yield,

or complication rates. The estimated blood loss was lower for robotic-assisted procedures with a lower transfusion rate, reaching statistical significance in one of the meta-analyses. The conversion rate to open surgery was found to be lower in patient operated with the DaVinci system (4.9 vs. 9.9%, $p = 0.06$ in the study by Gaia et al. [260] and OR 0.24; CI, 0.09–0.64 in the study by Reza et al. [261]). The comparison between robotic-assisted and open surgery showed significant prolongation of operation time when the robot was used. However, this was balanced by a reduction in perioperative complications, blood loss, transfusion rate, and length of stay, a motivating trade-off for the longer durations of surgery. The number of dissected lymph nodes was significantly higher in the robotic cases.

These reports support the feasibility and short-term safety of robotic surgery for endometrial cancer staging procedures. In view of the FDA approval in 2005, long-term oncologic outcomes have not yet been published, but short-term outcome with 2-year disease-free survival was reported to be at least as good as open surgery in one recent publication (236).

Ovarian Cancer

Robotic-assisted surgery has been reported to be adequate for surgical treatment and restaging procedures of early ovarian cancer.

However, it remains a challenge for advanced stage disease. The full staging of ovarian cancer requires access to all abdominal quadrants, making it frequently necessary to undock the robot at some stage of the surgery, insert additional trocars, move the robot or the operating table, and re-dock the arms to the trocars, with associated difficulties for anesthesia, the operating team, and arm collisions.

Recently, Magrina et al. (262) retrospectively compared the perioperative outcomes and survival of 25 patients who underwent robotic-assisted primary surgery for ovarian cancer with matched groups of patients that were treated by either laparotomy or laparoscopy. They concluded that laparoscopy or robotic surgery were superior to laparotomy for tumors requiring the excision of the primary tumor alone or with one additional major procedure. When the operation required two or more additional procedures, laparotomy was the preferred method of surgery. In this series, survival was not affected by the type of surgical approach.

A recent update (unpublished) on this patient series reveals a total of 32 patients with invasive epithelial ovarian cancer, 7 patients with stage IV disease, and 18 patients with stage III, half of whom had received neoadjuvant chemotherapy, and 4 patients were above the age of 80. Two patients underwent conversion at the end of the procedure to fully and safely remove

pelvic tumor invading the rectosigmoid. One 88-year-old patient succumbed to sepsis following bowel perforation.

Cost Analysis

The main barrier to the implementation of robotics mentioned repeatedly by health care professionals, administrators, and policymakers concerns the high upfront capital cost, the annual maintenance cost, and the cost of proprietary disposable robotic instruments. Using theoretic decision modeling, some groups found robotics not economically attractive compared to laparoscopy. On the other hand, when compared to laparotomy, the combination of reduced hospital stay and fewer complications in patients undergoing robotics contributes to an overall lower cost for the robotic-assisted procedures, as was demonstrated in patients undergoing radical hysterectomy for cancer of the cervix (248), and in patients undergoing staging procedures for endometrial cancer (236,263). The Canadian Agency for Drugs and Technologies in Health (264) recently published an in-depth economic analysis of robotics, revealing that a robotic surgery program becomes cost-effective once the annual caseload reaches close to 250 hysterectomies (the report is based on data combining hysterectomies for benign and malignant disease); also, the more the robot is utilized, either within a department or across surgical departments, the higher the achieved gains. As expected, the increased annual caseload dilutes the acquisition and maintenance cost, allowing the financial benefits per patient case to reach significant values. Careful selection of patients for whom the robotic approach yields the most prominent improved clinical impact, like the obese and the elderly patient populations, will further improve the economic value of using the robot. Overall, the economic advantages presented in most studies may underestimate the actual value, as only direct and indirect hospital costs were included without calculating the overall gains to the patient and society (i.e., quicker recovery and return to normal activities) (264).

The absence of randomized trials and the retrospective design of most case-control studies warrant cautious interpretation of the results. Despite the inconsistency and the methodological limitations, there is a clear trend indicating the improved perception of security and confidence to manage more complex cases with the robot. This has led to an increase in the proportion of patients benefiting from MIS following the introduction of robotics.

Single-Port Robotic Surgery

The use of a computer, integrated in robotic devices, appears to eliminate most of the ergonomic problems associated with SPLS. Several robotic systems designed specifically for single-port laparoscopy are currently under development and in early clinical trials (265). The present da Vinci system was successfully used for single-port surgery in various urologic procedures. Although technical difficulties were reported, the perioperative outcomes were comparable to conventional laparoscopy (266,267). In a pioneer study by Nam et al. (186), 7 patients underwent robotic total hysterectomy using a single-port transumbilical approach with a home-made multichannel port system and the da Vinci S system. Five patients underwent total hysterectomy for benign reasons; 1 had extra-fascial hysterectomy for carcinoma *in situ* of the cervix and 1 had radical hysterectomy, bilateral pelvic lymph node dissection, and paraaortic lymph node sampling for stage IB1 cervical cancer. One patient had to be converted to a 3-port robotic surgery due to severe pelvic adhesions resulting in significant intraoperative bleeding. Despite this encouraging report, the conventional da Vinci system was clearly not designed to be used as a single-port surgical system. The bulky arms and the

articulating but straight shaft instrument are limiting factors in single port usage.

A prototype single-port robotic system (single-site) was developed by Intuitive Surgical, as an add-on to the da Vinci Si system. The port has 5 channels. One channel is for an 8.5-mm scope, two for the robotic arms via curved crossing cannulae, one for the assistant port, and the fifth for CO₂ insufflation. The surgical instruments used are semi-flexible and cross each other at the insertion point to allow triangulation at the surgical field. At this time, the robotic arms lack the endowrist articulation feature. A uterine manipulator is used to maintain proper exposure (268). The prototype was used by Escobar et al. to perform total hysterectomy and bilateral salpingo-oophorectomy in 8 cadavers, with a success rate of 87.5%. Technical difficulties were noted in one cadaver, with an estimated BMI of 56, including complex docking and exposure problems. A second cadaver with previous midline abdominal surgery also presented problems for docking (269). The safety and feasibility of the single-site system was demonstrated by Konstantinidis et al. who reported the use of the system safely for cholecystectomy in 45 patients (270). The system appears to offer a wide range of motions, instrument and scope stability, improved ergonomics, and minimal instrument clashing.

A different approach is taken with the development of the single-port laparoscopy bimanual robot (SPRINT), which is specifically designed for SPLS (271), but *in vivo* trials are yet to be published.

The Future of Computer Interface

At present the robotic platform confers advantages of increased dexterity of the operating instruments, greatly enhanced three-dimensional immersed visual fields, and improved ergonomics for the surgeon. The introduction of this technology has greatly assisted centers in overcoming the technical challenges of laparoscopy and its steep learning curve, to be able to offer more MIS procedures to their patients. The single-port approach represents one of the new frontiers in MIS. It is facilitated by the computer interface in robotic platforms, and shows promise as a method to reach the various abdominal quadrants without the need for re-docking.

This, however, appears to represent only the tip of the iceberg, as the computer interface has the potential to greatly enhance the surgical capabilities by introducing digital analysis, image integration, feedback controls, surgical algorithms, and other technologies, mixing the power of the computer interface to literally expand surgical abilities beyond the human hand. Although at a different scale, this could be compared to the integration of computers in cars, airplanes, or, for that matter, almost any aspect of our modern life.

CONCLUSION

The movement toward MIS in gynecologic oncology is now irreversible. After the early demonstration of feasibility, it has become evident that magnification, lighting, and reduced capillary vessels bleeding provided a surgical advantage. There has been a growing level-I evidence of the short-term benefits, particularly in terms of patient pain, comfort, quality of life, and return to normal activity (272).

In parallel, a definitive reassurance that laparoscopic surgery does not impair the oncologic long-term outcome, provided that the standards are met, is now available. The patients may even benefit from the fact that postoperative chemotherapy or radiation therapy can be initiated earlier, and that complications arising from bowel adhesions are minimized.

Interestingly, the unequivocal benefit of MIS is in coherence with the trend toward shorter hospital stay imposed by the current financial constraint on health care cost. In the Ghezzi et al. experience (272), length of hospital stay has decreased significantly over time for all disease sites. The final achievement of the effort to reduce hospital stay is day surgery. The Toronto experience of day care major laparoscopic surgeries, including radical hysterectomies and aortic node dissection, shows that 48.5% of

303 patients had same-day discharge (median stay, 295 min). Among outpatients, seven (4.8%) were readmitted within 3 weeks of surgery. No patients with same-day discharge had a major acute postoperative complication (273). Another series of 18 outpatient extraperitoneal aortic dissections has also been reported (274).

Early criticisms that only carefully selected patients may benefit from laparoscopic surgery are now irrelevant. As soon

as the senior author implemented a program favoring laparoscopic surgery in a cancer center, over 90% of surgeries for uterine cancer were performed laparoscopically (275). In the Oslo University Hospital, records from all women having a hysterectomy due to premalignant or malignant endometrial changes during the years 2002 to 2009 were examined retrospectively. A total of 521 hysterectomies were performed during the study

period. While laparoscopy was performed in about 20% of the cases in the first 2 years, it increased to 83% in the last year of the period (276). A group in Italy recently reported on 383 consecutive women undergoing surgery for the treatment of an apparently early-stage gynecologic cancer. Integration of minimal access surgery proceeded sequentially to include endometrial, ovarian, and cervical cancer patients. The annual

proportion of laparoscopic cases has increased significantly over the study period from 7.7% in 2001 to 90.9% in 2008 (277). In contrast, only 7.7% of Californian endometrial cancer patients in a recent population-based study (278) were managed laparoscopically. The current place of robotic surgery is to continue to fill the gap and eventually benefit the patient. Ironically, the laparoscopic approach that has been considered for years as “investigational” is now referred to as “conventional laparoscopic surgery” as compared to robotic-assisted laparoscopic surgery. Today it is extremely clear that the 2 variants of laparoscopic approach are complementary, and that the choice between the 2 is mainly driven by surgeon preference generally related to training, and by the availability of the robot generally related to economic reasons. However, specific indications of robotic assistance, such as morbid obesity, are emerging. In the future, further sophistications of the robotic technology will allow for further developments of MIS in gynecologic oncology that will reduce the indications for laparotomy in gynecologic cancer patients.

FIGURE 10.5. Scientific peer reviewed publications on LESS in the PubMed database, presented as number per year.

INTRODUCTION

The objectives of imaging in gynecologic oncology are primary tumor detection and characterization, image-guided percutaneous biopsy, staging, monitoring treatment response, and detecting tumor recurrence. Comprehensive imaging of the female pelvis can be achieved using a combination of ultrasound (US), computed tomography (CT), magnetic resonance imaging (MRI), and combined 2- ^{18}F -fluoro-2-deoxy-D-glucose positron emission tomography computed tomography (FDG-PET/CT). The choice of imaging modality depends on the clinical question (Table 11.1). In some instances, more than one modality may be appropriate, and therefore it is best to discuss the clinical question with the radiologist to determine which modality will be most useful. As with any rapidly evolving technology, imaging strategies are not static and require continuous updating and reevaluation.

IMAGING MODALITIES, EXAMINATION TECHNIQUES, AND NORMAL ANATOMY

Ultrasound

Ultrasound (US) is considered the initial imaging modality of choice for evaluation of the female pelvis. Currently, the accepted roles of US in women with suspected gynecologic malignancy include characterization of adnexal masses, identification of endometrial abnormalities in women with intermenstrual or postmenopausal bleeding, and detection of primary or recurrent gestational trophoblastic disease in women with elevated serum beta human chorionic gonadotropin (β -hCG) levels. US is also used to guide biopsy of primary pelvic tumors and/or metastases (1) and to guide drainage of postoperative fluid collections such as lymphoceles, seromas, or abscesses. The role of US in screening high-risk patient populations for ovarian or endometrial carcinoma remains controversial.

US has many advantages in routine pelvic imaging: it is relatively inexpensive, provides multiplanar views, is widely available, and lacks ionizing radiation. Its portability allows it to be used in virtually any setting including the US suite, operating room, patient bedside, or radiation therapy suite. However, US also has a number of limitations: it is operator-dependent, and image quality varies with patient body habitus and presence of overlying bowel gas. Transvaginal ultrasound (TVS) provides the best spatial and soft-tissue resolution, but it comes at the cost of a significant decrease in the size of the field of view.

Sonohysterogram (SHG), which utilizes TVS while distending the endometrial cavity with fluid, can be useful in evaluating the endometrium.

Technique

Adequate US evaluation of the female pelvis requires a transvaginal approach. Placement of the transducer closer to the organs of interest allows use of a higher-frequency (typically 5.0- to 7.5-MHz) transducer. While the use of such a transducer results in significantly improved spatial resolution and fewer imaging artifacts in comparison to transabdominal imaging, it does so at the cost of a smaller field of view. Hence, transabdominal imaging must be considered an important complementary imaging technique if the mass is larger than the TVS field of view, the ovaries are displaced out of the pelvis, the ovaries are not visualized because of the presence of bowel gas, or to evaluate important ancillary findings such as hydronephrosis, ascites, peritoneal deposits, and liver metastases. Transabdominal imaging also provides a better overall view of the pelvis and the relationship of female pelvic organs to the pelvic sidewall and bladder. Transabdominal pelvic imaging is performed with a 3.5- to 5.0-MHz curved array transducer using a distended urinary bladder as an acoustic window to view the female pelvic organs. Three-dimensional US is a relatively new technique that has been shown to decrease scanning time and possibly improve diagnostic confidence in pelvic imaging (2,3). Color, power, and spectral Doppler provide additional information regarding associated vascularity.

SHG is increasingly performed to improve the evaluation of the endometrium. With this technique, sterile saline is infused into the endometrial cavity under continuous TVS guidance. The sterile saline distends the endometrial cavity, separating the anterior and posterior endometrial layers and outlining the endometrial surface (4,5). Contraindications to SHG include hematometra and acute pelvic inflammatory disease. Three-dimensional SHG reduces operator dependence and length of examination time and has been reported to provide significant additional information in a majority of patients (6).

Normal Anatomy

The normal myometrium is homogeneous in echotexture and intermediate in echogenicity. Anechoic tubular structures separating the outer one-third from the inner two-thirds of the myometrium represent the arcuate vessels, which are best seen on color flow imaging. The internal os can be recognized as a slight constriction of the uterine contour.

The endometrium should be measured at the thickest part of the endometrial stripe in the uterine fundus on a midline sagittal image and, by convention, is always reported as a double-layer

Table 11.1 The Choice of Imaging Modality in Endometrial, Cervical, and Ovarian Cancer				
Pathology	Imaging Modalities			
	US (TA/TVS/SHG)	CT	MRI	PET/CT
Endometrial Cancer	Evaluation of the endometrium in patients presenting with postmenopausal bleeding Double-layer endometrial thickness >5 mm on TVS determines the need for endometrial sampling	Detection of enlarged lymph nodes Detection of distant metastases (lung, liver, etc.) Identification of peritoneal nodules in serous papillary and clear cell carcinoma Detection of recurrent pelvic and distant metastatic disease	Delineating the origin of the primary tumor (endometrial vs. cervical) when the biopsy results are inconclusive Assessment of the depth of myometrial invasion and cervical stromal invasion (improves pretreatment risk stratification) Evaluation of disease extent in the pelvis Detection of enlarged lymph nodes Evaluation of surgical resectability, if pelvis is the sole site of recurrence	Detection of extrauterine disease Monitoring treatment response in selected cases Detection of distant metastases in patients with suspected recurrence within the pelvis; detecting unsuspected distant metastases significantly alters treatment choices
Cervical Cancer	No role apart from evaluation of complications such as hydronephrosis and guiding interventional procedures	Evaluation of extent of disease in advanced cases (especially if no access to MRI) Detection of enlarged lymph nodes Detection of distant metastases (lung, liver etc.)	Accurate evaluation of tumor size (particularly important in cases considered for trachelectomy) Evaluation of parametrial invasion Evaluation of pelvic sidewall invasion and bladder/rectal mucosa invasion Detection of enlarged lymph nodes Brachytherapy treatment planning Monitoring response to chemoradiotherapy Evaluation of surgical resectability, if pelvis is the sole site of recurrence May distinguish radiation fibrosis from recurrent disease	Evaluation of patients with advanced cervical cancer, especially the detection of lymph node metastases Radiotherapy field planning Evaluation of response to treatment May distinguish radiation fibrosis from recurrent disease Detection of distant metastases in patients with suspected recurrence within the pelvis; significantly alters treatment choices
Ovarian Cancer	Detection and characterization of adnexal masses Screening of women at high risk for ovarian carcinoma Guide omental/peritoneal biopsy and drainage of ascites	Characterization of ovarian lesions that are detected incidentally on CT Triage patients to primary surgery versus neoadjuvant chemotherapy by accurate evaluation of the extent and anatomical location of peritoneal spread (dictates the feasibility of cytoreductive surgery) Detect enlarged lymph nodes Detect complications such as small bowel obstruction Evaluation of residual disease following surgery Evaluate treatment response and assess suspected relapse with rising CA-125 levels or clinically suspicious symptoms Guide omental/peritoneal biopsy	Characterization of indeterminate adnexal lesions on US Evaluation of disease in situations where CT is contraindicated (contraindications to contrast media, renal insufficiency, and pregnancy) Evaluate resectability of a pelvic recurrence if surgery is planned	May play a role in evaluation of the extent of disease Evaluation of recurrent ovarian cancer especially in patients with elevated CA-125 but negative CT findings

measurement. The normal endometrium is echogenic. However, the thickness and echotexture of the endometrium vary with the hormonal status of the patient. At the end of the menses, the endometrial stripe is highly echogenic and measures approximately 2 to 3 mm (Fig. 11.1). During the secretory stage, the endometrium becomes less echogenic and thickens, reaching

a maximum of 8 mm (Fig. 11.1). Before ovulation, a trilaminar appearance of the endometrium has been described. The central thin echogenic line represents a reflective artifact and/or mucus and secretions between the anterior and posterior layers of the endometrium. Subjacent is the second layer, which is the relatively hypoechoic functionalis layer. The third layer is the surrounding

FIGURE 11.1. Normal uterus and ovary on ultrasound. Longitudinal TVS image (A) demonstrating normal uterine anatomy. Uterine myometrium demonstrates a homogeneous echotexture (* in A). The endometrium is a highly echogenic thin line (arrows in A) at the end of menstruation. Longitudinal TVS image (B) in a different patient demonstrates a normal endometrium (arrows in B) in the secretory phase. Transverse TVS image (C) demonstrates a normal ovary (arrow in C) in a premenopausal patient. Ovarian parenchyma demonstrates a homogeneous echotexture with multiple anechoic follicles.

deeper basalis layer, which remains echogenic. Following ovulation, the functionalis layer becomes thicker and more echogenic than during the proliferative phase, and the entire stripe may reach 15 mm in thickness and is more uniformly echogenic just prior to menstruation (7). In some patients, the innermost layer of myometrium is relatively hypoechoic compared to the immediately adjacent endometrium and is termed the subendometrial halo. The subendometrial halo is less commonly visualized in postmenopausal women. Neither the subendometrial halo nor fluid or debris within the endometrial cavity should be included in measurements of the endometrial stripe. At SHG, the endometrium should be homogeneous, symmetric, and regular without mass effect (Fig. 11.2). The sum of the width of the two layers should not exceed the maximum acceptable width for the patient's hormonal status.

In postmenopausal women, the uterine corpus atrophies until it approximates the length of the cervix. Similarly, there is atrophy of the endometrium which appears as a thin, regular echogenic line <5 mm in width (8). In women taking hormonal replacement therapy (HRT), less uterine and endometrial atrophy occurs (9). Women taking sequential HRT are best examined following withdrawal bleeding and the progesterone phase of their cycle when the endometrium is expected to be at the thinnest.

The US appearance of the ovaries also changes with the patient's hormonal status. The premenopausal ovary has a relatively homogeneous outer cortex with a more echogenic central stroma. Small anechoic follicles are commonly seen peripherally (Fig. 11.1). At

ovulation, one follicle becomes dominant, reaching a maximum diameter of 2.0 to 2.5 cm. Following ovulation, the corpus luteum develops. The corpus luteum may contain debris and/or hemorrhage and often involutes, appearing to be crenelated just prior to menstruation. The ovaries atrophy with menopause and contain fewer follicles. Therefore, postmenopausal ovaries are more difficult to visualize with US. In women taking HRT, less ovarian atrophy will occur and follicles will continue to develop.

Doppler evaluation of ovarian blood flow is best performed during days 3 to 7 of the menstrual cycle. The ovary undergoing ovulation in a given cycle demonstrates a relatively high-velocity, low-resistance arterial waveform with continuous forward diastolic flow. The contralateral ovary will typically demonstrate a higher-resistance, low-velocity arterial waveform with either very low or no diastolic flow.

Computed Tomography

CT is the primary imaging modality for staging and treatment follow-up of patients with ovarian cancer. It is also routinely used for detection of distant metastatic disease and lymphadenopathy in patients with advanced endometrial, cervical, and vulvar cancer as well as detection of recurrent gynecologic malignancies. CT rather than US-guided biopsy can be useful masses that are small and/or difficult to access (1,10–12).

Advantages of CT include ready availability, short image acquisition times, large field of view, high spatial resolution, and rapid three-dimensional (3-D) reconstructions. Disadvantages

FIGURE 11.2. Normal sonohysterogram. Longitudinal SHG images (A, B) demonstrate a fluid-filled endometrial cavity (arrows in A). Catheter (arrows in B) is seen within the lower uterine segment.

of CT include the use of ionizing radiation, degradation of image quality by patient body habitus or metallic implants, such as a hip prosthesis, and the morbidity and mortality associated with iodinated contrast agents.

Technique

Contrast-enhanced CT of the abdomen and pelvis is performed in the portal venous phase, 70 seconds following an injection of intravenous low osmolar contrast medium; this enhances blood vessels and viscera, allowing easier identification of enlarged lymph nodes and parenchymal lesions, especially in the liver and spleen. Oral contrast medium is utilized to opacify the small and large bowel, which allows detection of bowel serosal deposits. In some centers, patients receive 500 mL of diluted oral contrast medium the evening preceding the examination and an additional 500 mL, 45 minutes before the CT scan. In other protocols, the patient receives 600 to 1,000 mL of dilute oral contrast at least 1 hour before the examination, coupled with a 200-mL dilute contrast enema.

Normal Anatomy

On CT, the vagina, cervix, and uterine corpus can be differentiated based on both morphologic and enhancement characteristics (Fig. 11.3). The uterine corpus appears as a triangular or ovoid soft-tissue mass posterior to the urinary bladder. The cervix is a more rounded structure. At the level of the fornix, the vagina has a flat rectangular or crescentic shape. Following bolus intravenous contrast administration, the myometrium in the uterine corpus enhances to a greater degree than that of the cervix (Fig. 11.3). The endometrium can often be delineated from the enhancing myometrium. The broad and round ligaments can be seen coursing laterally and anteriorly, respectively. Occasionally, the uterosacral ligaments are depicted as arc-like structures extending from the cervix to the sacrum.

In the premenopausal patient, the normal ovaries are routinely seen, usually posterolateral to the uterine corpus and medial to the external iliac vessels (Fig. 11.3). Their uniform soft-tissue density is punctuated by small cystic regions representing follicles. In the postmenopausal patient, the ovaries are small and less readily detected.

Magnetic Resonance Imaging

MRI is the modality of choice for staging of uterine corpus and cervix malignancies. MRI has been shown to be superior to CT

for staging of endometrial and cervical cancers (13,14), and may be useful for staging of ovarian cancer in selected patients. In addition, MRI can often differentiate radiation fibrosis from recurrent tumor (15) and is useful in the detection of recurrent gynecologic malignancies. The accuracy of MRI assessment of lymph node involvement is similar to that of CT; both rely on size criteria to detect lymphadenopathy (16).

Although MRI is still relatively expensive, it minimizes costs in some clinical settings by limiting or eliminating the need for more expensive and/or more invasive diagnostic or surgical procedures (17,18). There are at least three cost-minimizing indications for MRI in the evaluation of women with gynecologic malignancy: (a) staging of invasive cervical carcinoma as an adjunct to clinical examination; (b) the preoperative management of women with endometrial cancer (19-21); and (c) the characterization of indeterminate adnexal lesions on US (18,22).

Advantages of MRI include superior soft-tissue contrast, absence of ionizing radiation, and multiplanar capability. MRI is the modality of choice for patients with allergies to iodinated intravenous contrast media or renal impairment. However, clinicians should be aware that gadolinium contrast agents used in MRI have recently been associated with the development of nephrogenic systemic fibrosis (NSF), a rare progressive connective tissue disease, in patients with end-stage renal disease and/or acute renal failure. One disadvantage of MRI relative to CT is the need for longer acquisition times. In addition, MRI is contraindicated in patients with pacemakers, cochlear implants, certain vascular clips, metallic objects in the eye, and neural stimulators. Furthermore, some patients may experience claustrophobia and may require sedation in order to complete a diagnostic examination.

Technique

Patients are asked to fast for 4-6 hours prior to MRI examination in order to limit motion artifacts from bowel peristalsis (23). An antiperistaltic agent, such as glucagon or hyoscine butyl bromide, is recommended to further reduce motion artifacts (24). The patient is asked to void before the examination, as a full bladder may cause ghosting and motion artifacts that degrade images. Patients are imaged in the supine position using a pelvic surface array multichannel coil (e.g., a cardiac coil usually offers the best image quality) (23,25). Endoluminal coils (endorectal and endovaginal) can provide high-resolution images of small tumors of the cervix and aid detection of early parametrial invasion (26,27). However, their field of view is limited in assessing

FIGURE 11.3. Normal uterus and ovary on CT. Axial contrast-enhanced CT image (A), sagittal (B), and coronal reformatted (C) CT images demonstrate a normal uterus (white arrow in A, B, C) and ovaries (black arrows in C). Note that the cervix (black arrow in B) enhances less avidly than the myometrium (white arrow in B); this should not be mistaken for cervical pathology. Both ovaries (black arrows in C) are seen as soft-tissue attenuation ovoid structures adjacent to the uterus. They contain small cystic spaces corresponding to follicles.

large tumors, extra-uterine extension to adjacent organs and the pelvic sidewall, and detecting pelvic lymph nodes; consequently, endoluminal coils are not widely used in gynecological imaging. Vaginal opacification with gel, yielding high signal intensity on T2-weighted images (T2WI), may be useful in cases where there is suspected cervical tumor extension into the vagina, particularly into the posterior vaginal fornix (28).

The basic imaging protocol for gynecological MRI includes T1-weighted images (T1WI) of the pelvis in the axial plane and T2WI in the axial and sagittal planes. When T1WI shows high signal intensity within the adnexa, which may represent fat or hemorrhage, fat-saturation T1-weighted images (T1W FS) are mandatory to differentiate between the two. Staging of gynecological malignancies requires large field of view axial T1WI and/or T2WI of the pelvis and abdomen to identify enlarged lymph nodes, hydronephrosis, as well as bone marrow changes (20,29). High resolution, small field of view, axial oblique (short axis) T2W fast spin-echo (T2W FSE) images taken parallel to the short axis of the uterine corpus are essential to accurately evaluate the depth of myometrial invasion in endometrial carcinoma (30). In the assessment of patients with cervical cancer, high resolution small field of view axial oblique (short axis) T2W FSE images parallel to the short axis of the cervix are crucial for identification of parametrial invasion (31).

Dynamic multiphase contrast-enhanced MRI, using 3-dimensional gradient echo T1WI, after intravenous gadolinium administration, is often performed in staging patients with endometrial cancer. It is useful in the characterization of complex adnexal lesions, and can aid detection of small peritoneal

and serosal implants, when ovarian cancer is suspected (32,33). Routine use of dynamic multiphase contrast-enhanced 3D T1-weighted sequences is not recommended for staging patients with cervical carcinoma. However, these sequences may be very useful for accurate delineation of small cervical tumors in patients being considered for fertility sparing surgery (i.e., trachelectomy) (34) and to differentiate tumor recurrence from radiation fibrosis in patients with cervical cancer (15).

Increasingly, diffusion-weighted MRI (DW-MRI) is routinely incorporated in MRI staging protocols for uterine malignancies. DW-MRI can be useful for accurately determining the depth of myometrial invasion in patients with endometrial cancer. It can be particularly helpful for tumors that are either iso- or hyper-intense relative to the myometrium on T2WI or when the use of intravenous contrast medium is contra-indicated, and it may replace dynamic imaging in the future (35,36). DW-MRI may also improve detection of drop metastases in the cervix or metastatic foci outside the uterus, such as in the adnexa or peritoneum (35–37).

Normal Anatomy

Pelvic anatomy is exquisitely depicted on MRI. On T1WI, the normal pelvic musculature and viscera demonstrate homogeneous low to intermediate signal intensity. Cortical bone demonstrates low signal intensity, and fatty marrow is high in signal intensity. Similarly, intrapelvic fat demonstrates high signal intensity. It is the soft-tissue contrast provided by the T2WI, however, that is the basis for the strength of MRI in pelvic imaging. On T2WI, the uterus, cervix, and vagina all exhibit distinct

FIGURE 11.4. Normal uterus and ovary on MRI. Sagittal (A, B) and axial (C) T2W FSE MR images through the pelvis demonstrate normal uterus (*anteverted* in A, *retroverted* in B) and ovary. The uterine zonal anatomy is seen with the intermediate signal intensity outer myometrium (* in A, B), low signal intensity junctional zone (*black arrow* in A, B), and high signal intensity endometrium (*short white arrow* in A, B). Plicae palmatis are also elegantly demonstrated (*white long arrow* in B) in the cervix. Normal ovary (*white arrow* in C) demonstrates an intermediate signal intensity stroma and multiple high signal intensity follicles.

layers of different signal intensity—the so-called zonal architecture. The endometrium shows high signal intensity, while the outer myometrium is intermediate in signal intensity, being higher in signal intensity than striated muscle (Fig. 11.4). Interposed between these two layers is a narrow band of lower signal intensity, the junctional zone, which corresponds to the innermost myometrium. The low signal intensity of the junctional zone reflects its low water content relative to the rest of the myometrium, which may be a function of its lesser amount of extracellular matrix per unit volume (38,39). The three zones seen on MR images are not comparable to the different zones seen on US (40). MRI provides good visualization of the endometrium, including the varying width of the endometrium (both leaflets) seen with the menstrual cycle (41). In postmenopausal women not receiving exogenous hormones, uterine zonal anatomy is indistinct, and the endometrium typically measures less than 5 mm (41).

The cervix also demonstrates zonal architecture on T2WI (Fig. 11.4). There is an inner area of high signal intensity, which represents epithelium and mucus, and an outer area of predominantly low signal intensity, which represents fibrous cervical stroma (42,43). Interposed between the high signal intensity endocervical canal and the low signal intensity fibrocervical stroma is a feathery layer of intermediate signal intensity, which

represents the mucosal folds or plicae palmatae. The vagina demonstrates two zones on T2WI, the bright vaginal mucosa and the intermediate signal intensity vaginal wall.

Following the administration of intravenous gadolinium, the zonal anatomy of the uterus is demonstrated on fat-saturated T1W images. The normal endometrium and outer myometrium enhance to a greater extent than the junctional zone. Similarly, in the cervix, the inner cervical mucosa and outer smooth muscle enhance more than the fibrocervical stroma. The parametrial tissues, vaginal wall, and submucosa also enhance after gadolinium administration.

The ovaries display homogeneous low to intermediate signal intensity on T1WI, whereas on T2WI, the follicles appear brighter than the surrounding stroma (Fig. 11.4). The normal fallopian tubes are not routinely seen unless they are dilated.

Positron Emission Tomography/ Computed Tomography

The main applications of FDG-PET/CT in gynecologic oncology are staging of cervical cancer and detection of recurrent ovarian, cervical, and endometrial cancer. FDG-PET/CT is the

only modality that combines the biochemical change (the accelerated rate of glycolysis) associated with malignancy with the structural changes visualized at CT. FDG-PET does not have the same spatial resolution or soft tissue contrast as US or MRI, but image fusion techniques that overlay FDG-PET images onto MR images are available. A disadvantage of FDG-PET/CT is that false negatives can occur with lesions smaller than 0.5 cm and with certain tumor types that demonstrate low metabolic activity. In addition, false-positive results can be seen with inflammatory or infective etiology, postoperative changes, or reactive lymphadenopathy, including chronic inflammatory disorders such as granulomatous disease.

Technique

Patient preparation is crucial to high-quality FDG-PET/CT imaging. Physiologic uptake of tracer is prominently seen in the brain, salivary glands, myocardium, liver, and spleen. The gastrointestinal tract can also show variable uptake which, if prominent, can limit assessment of implants. FDG is excreted by the kidneys, and therefore, intense uptake can be seen in the renal collecting systems, ureters, and bladder that can sometimes limit assessment of disease in the pelvis due to scatter. Bladder catheterization and use of diuretics have been recommended by some, but their use may not be feasible in all cases. Uptake in skeletal muscles may be increased due to physical activity and brown fat, making assessment of lesions difficult. In premenopausal patients, increased physiologic uptake of FDG can occur in the endometrium and ovaries during the menstrual cycle and may cause false positive findings.

The patient is asked to fast for at least 4 hours prior to the FDG-PET/CT examination in order to keep insulin levels low. Elevated insulin levels drive FDG into skeletal muscle, often leading to nondiagnostic examinations. Blood glucose is checked before FDG injection; if the blood glucose is above the recommended level of 200 mg/dL, the study is generally not performed. Specific protocols are used for diabetic patients.

Steps are taken to reduce the amount of bladder activity, including adequate hydration and voiding immediately before imaging. Intravenous hydration may be used, but dextrose should not be given. Patients are asked not to engage in any heavy activity or gum chewing prior to the FDG-PET/CT exam. About 10-20 mCi of FDG is given intravenously, and the patient is asked to lie or sit quietly without talking in order to limit skeletal muscle FDG uptake. Imaging generally commences 45-60 min after FDG injection and lasts 20 to 45 min, depending on the specific protocol.

The amount of FDG uptake in tumors is assessed using a semiquantitative measure called the standardized uptake value (SUV). The SUV is the FDG activity (kBq/ml) divided by the total injected dose (MBq) and multiplied by the body weight. This value represents the metabolic activity of malignant lesions; thus, a change in tumor SUV after treatment reflects metabolic progression or remission. According to the PERCIST criteria for therapy response assessment, a 30% decrease in SUV is considered evidence of partial metabolic response, whereas an increase of 30% is regarded as evidence of progression (44).

Normal Anatomy

In premenopausal patients, uterine and ovarian FDG uptake is related to the menstrual cycle. Ovarian FDG uptake occurs in the late follicular to early luteal phase of the menstrual cycle. The most intense endometrial FDG uptake occurs during the first 3 days of the menstrual cycle (45). Therefore, premenopausal patients should be imaged a week before to a few days after menstruation. There is no physiologic uptake of FDG in the uterus or ovaries of postmenopausal patients (45).

ENDOMETRIAL CANCER

Introduction

Endometrial carcinoma is typically diagnosed by endometrial biopsy, or dilation and curettage (D&C). TVS is the initial imaging modality to evaluate the endometrium, especially in patients presenting with postmenopausal bleeding. MRI is the imaging modality of choice for the evaluation of the extent of disease (36, 46-51). CT is used to identify peritoneal nodules in serous papillary and clear cell carcinoma of the endometrium as well as for evaluation of distant metastatic disease and lymphadenopathy. CT, MRI, and PET/CT, individually or in combination, depending on the clinical question, are useful in the evaluation of recurrent disease.

Primary Diagnosis of Endometrial Cancer

TVS and/or SHG are routinely used to evaluate the endometrium in patients presenting with postmenopausal bleeding (52-55). Double-layer endometrial thickness ≥ 5 mm on TVS is used as the sole US criterion for determining whether endometrial sampling is warranted in postmenopausal patients (54,56,57). However, the specificity of this threshold is low, ranging from 59% to 63% (54,58). In a meta-analysis of 35 studies including 5,892 women, Smith-Bindman et al (54), reported that using a cut-off of 5 mm for endometrial thickness, 96% of women with endometrial cancer had an abnormal TVS. In this series, a woman with a 10% pretest probability of endometrial carcinoma and a negative TVS had a posttest probability of endometrial carcinoma of only 1%. They concluded that TVS is highly accurate in identifying a subgroup of patients at extremely low risk, obviating the need for endometrial sampling in these patients.

In women taking HRT, the specificity of the 5 mm cut-off is even lower, as HRT increases endometrial thickness. However, since the pretest probability of endometrial carcinoma is also likely increased in these patients, the same cut-off value of ≥ 5 mm is generally used. In women on sequential HRT regimens, scanning should be performed after the progesterone part of the cycle when the endometrium is expected to be at its thinnest. Breast cancer patients on tamoxifen treatment can have thickened endometrium with tiny cystic spaces. The risk of endometrial cancer increases with total duration of tamoxifen use and cumulative dose, prior estrogen replacement therapy, etc.

On US, endometrial cancer appears as an irregular, heterogeneous mass with increased vascularity on both Doppler and color flow imaging (Fig. 11.5) (59-61). The most specific and only reliable US finding for endometrial carcinoma is invasion of the myometrium indicated by the disruption of the subendometrial halo by an endometrial mass. On SHG, endometrial carcinoma is most commonly depicted as a broad-based, irregular mass (Fig. 11.5) (56). Difficulty in distending the endometrial cavity has also been described (62). Three-dimensional SHG has been reported to be more accurate than either TVS or two-dimensional (2-D) SHG for the diagnosis of endometrial carcinoma, but is rarely used.

Staging Endometrial Cancer

Staging of endometrial carcinoma is performed using the International Federation of Gynecology and Obstetrics (FIGO) surgical-pathological staging system, revised in 2009 (63). Full FIGO staging comprises a total abdominal hysterectomy (TAH), bilateral salpingo-oophorectomy (BSO), peritoneal washings, and retroperitoneal lymph node dissection. Imaging is not part

FIGURE 11.5. Stage IA endometrial carcinoma. Sagittal gray scale ultrasound image (A), sagittal color Doppler image (B), and sagittal SHG image demonstrate marked thickening of the endometrium (T in A, B) with associated increased blood flow (B). Note the thickened, irregular endometrium (white arrows in C) on SHG. Balloon catheter can be seen in the lower uterine segment.

of the FIGO staging system for endometrial cancer, but both MRI and CT are increasingly playing a crucial role in risk stratification and surgical treatment planning (64).

Ultrasound

US has little role in staging endometrial carcinoma. However, in centers with no access to MRI, US may be of value for assessing the presence of myometrial invasion in stage I disease. Myometrial invasion is documented when the tumor mass disrupts the subendometrial halo and/or extends into the subjacent myometrium. TVS has been reported to have a sensitivity of 77% to 100%, a specificity of 65% to 93%, and an overall accuracy of 60% to 76% in assessing the degree of myometrial invasion (65). Assessment of myometrial invasion is more difficult when the myometrium is thinned or distorted by fibroids (66). Three-dimensional SHG has been reported to be more accurate than TVS in detecting myometrial and cervical invasion by endometrial carcinoma (67).

Computed Tomography

CT is most commonly used in the assessment of advanced disease and performs as good as MRI in identifying extrauterine spread and enlarged lymph nodes (65). On contrast-enhanced CT, endometrial cancer is usually of slightly lower attenuation than the myometrium, but delineation of the tumor is difficult as there is relatively little contrast difference between tumor and the myometrium (68). CT is not sensitive or specific enough

to assess the depth of myometrial invasion or cervical stroma involvement (69). For detection of deep myometrial invasion, the sensitivity and specificity are 83% and 42%, respectively (69), with an overall staging accuracy of 58% to 76% (70).

Magnetic Resonance Imaging

Almost all patients with endometrial cancer undergo surgery as their primary treatment, during which the FIGO staging information is obtained. Therefore, the role of pretreatment MRI in endometrial cancer continues to be debated (21). However, only a relatively small percentage of patients have disease beyond the uterus (71). There is considerable controversy regarding systematic lymphadenectomy, with conflicting evidence regarding the survival benefits associated with the procedure (72–75). In addition, many patients with endometrial cancer have high surgical risks secondary to obesity, diabetes, and cardiovascular disease. Due to these factors, the extent of surgery is individualized in clinical practice: (a) Patients with a low risk of disease beyond the uterus may undergo more limited surgery, possibly involving minimally invasive surgical techniques and avoiding lymphadenectomy, thus reducing the risk of complications, particularly in high surgical risk cases; and (b) patients with a risk of disease beyond the uterus undergo complete surgical staging.

Prognostic features that predict disease beyond the uterus include the tumor histology and the presence of lymphovascular space invasion, deep myometrial invasion, and cervical involvement. Assessment of these factors together allows preoperative risk stratification for surgical planning. Of these four important

prognostic factors, only one is available preoperatively without the help of imaging: tumor histology, including grade and cell type, is available following pipelle or hysteroscopic sampling, although sampling error results in approximately 15% of cases being up-graded at the final histology (76). Lymphovascular space invasion is the single best predictor of nodal involvement, but its presence can only be determined after hysterectomy.

MRI can accurately assess the depth of myometrial invasion and cervical stromal invasion, which in turn correlate with the likelihood of lymph node metastasis and overall patient survival (50,77). Hence, in combination with tumor histology and grade, MRI aids the patient's preoperative risk stratification and ultimately guides treatment planning. The National Cancer Institute in France has recently incorporated MRI into the standard preoperative assessment of patients with endometrial carcinoma (78). The European Society for Urogenital Imaging (ESUR) also recommends MRI for staging of high-grade endometroid adenocarcinomas (type I histology) as well as serous papillary and clear cell adenocarcinomas (type II histology) (20).

MRI can be also very useful in patients with low-grade endometrial carcinoma who wish to preserve their fertility. The goal is to exclude any myometrial invasion so these patients can undergo treatment with high-dose progesterone and endometrial re-sampling. Finally, MRI is valuable in determining the site of origin of newly diagnosed uterine adenocarcinoma (corpus vs. cervix) when clinical and/or histologic evaluation is indeterminate (79).

Criteria for MRI interpretation according to tumor stage

MRI criteria for evaluation of endometrial cancer follow the FIGO staging system (Table 11.2) (63). Endometrial cancer is usually isointense to the myometrium on T1WI and of lower

signal intensity than the endometrium on T2WI. On dynamic multiphase contrast-enhanced 3D T1WI, the tumor enhances homogeneously, more slowly, and less avidly than the adjacent myometrium. On DW-MRI, the tumor is of high signal intensity with corresponding low signal intensity (restricted diffusion) on the apparent diffusion coefficient (ADC) maps.

Stage I tumors are confined to the uterine corpus and account for more than 80% of cases. Stage IA includes disease involving the endometrium, seen as focal or diffuse thickening of the endometrium as well as disease which invades less than 50% of the myometrium. Tumor that invades more than 50% of myometrium represents stage IB disease (Fig. 11.6). Delayed postcontrast 3D T1W images (2-5 minutes post gadolinium injection) facilitate evaluation of deep myometrial invasion, since these images provide maximum tumor-to-myometrium contrast (Fig. 11.6). This increases staging accuracy in cases where the tumor signal intensity is isointense to normal myometrium on T2WI or where tumor extends into the uterine cornu, when it can be difficult to accurately evaluate the depth of myometrial invasion on T2WI alone due to myometrial thinning (46,49,51,80-84). However, one must be cautious as peritumoral inflammation can lead to overestimation of the depth of invasion on contrast-enhanced images. Other reported pitfalls in assessing the depth of myometrial invasion in endometrial carcinoma include leiomyomas, adenomyosis, loss of junctional zone definition, and myometrial compression by polypoid tumor. These can also be minimized by the addition of dynamic multiphase contrast-enhanced 3D T1WI and DWI to T2WI (36,48,83-85). For assessing the depth of myometrial invasion, reported sensitivities of MRI range from 70% to 95%, while reported specificities range from 80% to 95% (36,50,51,83,86).

Stage II disease is characterized by direct invasion of the cervical stroma. On T2WI, cervical stromal invasion is represented by intermediate to high signal intensity tumor disrupting the normal low

Table 11.2 FIGO Staging of Endometrial Carcinoma with Corresponding MRI Findings

FIGO Stage	Description of Stage	MRI Findings
Stage I	Tumor confined to the corpus uteri	
IA	Tumor extending to <50% of myometrial depth	Abnormal signal intensity extends into the <50% of myometrium
IB	Tumor extending to ≥50% of myometrial depth	Abnormal signal intensity extends into >50% of myometrium
Stage II	Tumor invades cervical stroma, but does not extend beyond the uterus	Disruption of low signal intensity cervical stroma by tumor. A widened internal os with tumor protruding into the endocervical canal does not represent stromal invasion
Stage III	Local and/or regional spread of the tumor	
IIIA ^a	Tumor invades the serosa of the corpus uteri and/or adnexae	Disruption of continuity of outer myometrium. Irregular uterine configuration
IIIB	Vaginal and/or parametrial involvement	Segmental loss of hypointense vaginal wall
IIIC	Metastases to pelvic and/or paraaortic lymph nodes	Regional or paraaortic nodes >1 cm in short axis diameter. Additional suspicious features include: multiple small rounded lymph nodes, irregular lymph node contour, abnormal signal intensity similar to that of the primary tumor, presence of necrosis
IIIC1	Positive pelvic nodes	
IIIC2	Positive paraaortic lymph nodes +/- positive pelvic lymph nodes	
Stage IV	Tumor invades bladder and/or bowel mucosa, and/or distant metastases	
IVA	Tumor invasion of bladder and/or bowel mucosa (biopsy proven)	Abnormal signal intensity disrupts normal low signal intensity bladder/rectal mucosa. Note that bullous edema does not indicate stage IVA
IVB	Distant metastases, including intra-abdominal metastases and/or inguinal lymph nodes	Tumor in distant sites or organs

^aPositive cytology obtained at peritoneal washings should be recorded, but does not alter any stage.

FIGURE 11.6. Stage IB endometrial carcinoma. Sagittal and axial T2W FSE (A, E), sagittal and axial gadolinium-enhanced 3D T1W GRE (B, F), DW (C, G) MR images and the corresponding ADC maps (D, H) show an endometrial carcinoma (T in A-H) which extends into the outer myometrium (arrow in A-H). Deep myometrial invasion was confirmed at histopathology.

signal intensity cervical stroma. The enhancement of cervical mucosa on the delayed phase (2-5 minutes) can confidently exclude cervical stroma invasion (68). In detecting invasion of the cervical stroma, MRI has overall accuracy of 90% to 92% with sensitivity and specificity of 75% to 80%, and 94% to 96%, respectively (49–51).

Stage III is classified as locoregional spread of disease. In stage IIIA disease, there is invasion of uterine serosa or adnexa (Fig. 11.7). Disruption of the low signal intensity uterine serosa and/or irregular uterine contour on T2WI (Fig. 11.7) and the loss of the normal rim of brightly enhancing myometrium on dynamic multiphase contrast-enhanced 3D T1WI indicate

serosal involvement. Tumor deposits may be identified in the adnexa, even in the absence of serosal invasion, especially with high-grade, clear cell or serous papillary tumors (Fig. 11.7); DWI can aid detection in these cases (36). In stage IIIB disease, tumor extends into the upper vagina or parametria (Fig. 11.8), either directly or as metastatic disease. It is of paramount importance that the surgeon is made aware of parametrial invasion, as in its presence, a simple hysterectomy will not be possible and a more radical surgical approach will be required. The presence of enlarged regional lymph nodes indicates stage IIIC disease (IIIC1 involving pelvic nodes; IIIC2 involving paraaortic nodes with or

FIGURE 11.7. Stage IIIA endometrial carcinoma. Sagittal T2W FSE MR image (A) shows a tumor deposit on the serosa of the sigmoid colon (M in A) from a grade 3 endometrioid endometrial carcinoma (T in A). Axial T2W FSE MR image (B) in a different patient shows a clear cell endometrial carcinoma (T in B) with metastases to both ovaries (M in B).

without pelvic nodal involvement). A short-axis diameter of 1 cm or greater is used to diagnose nodal involvement on MRI (49,87).

Stage IV is defined by tumor extension beyond the true pelvis or invasion of the bladder or rectal mucosa. On MRI, loss of low signal intensity of the bladder or rectal wall and tumor invading the mucosa indicate stage IVA disease. Bullous edema of the bladder is a frequent sign of tumor in the subserosal or muscular layer of the bladder, but does not qualify for stage IVA disease. In stage IVB disease, distant metastases (including nodal enlargement above renal veins or in the inguinal region), malignant ascites, or peritoneal deposits are present. The latter are more common with high-grade, clear cell or serous papillary tumors, as clinically, they behave like ovarian cancer with a propensity to spread along the serosal and peritoneal surfaces. Distant metastases (lung, liver, and bone) is rare at presentation.

Positron Emission Tomography/ Computed Tomography

For initial staging, FDG-PET/CT has a limited role in assessing primary tumor extension within the pelvis (88). The primary role for FDG-PET/CT in staging of endometrial carcinoma is

detection of nodal disease. Direct comparison of MRI with FDG-PET/CT has demonstrated no statistically significant difference in the detection of lymph node metastases in patients with endometrial cancer (89). The added value of FDG-PET/CT is the detection of distant metastatic deposits, for which it has been found to have sensitivity of 100% and specificity of 94% (89). Kitajima et al. demonstrated that the sensitivity of FDG-PET/CT in detecting involved nodes of 4 mm or less was 16.7%; for nodes measuring 5 to 9 mm, the sensitivity was 66.7%; and for nodes 10 mm or greater, it rose to 93.3% (90). For nodal metastases, a sensitivity of 50% and a specificity of 86% have been reported, on a per patient basis. Overall, the sensitivity of FDG-PET/CT for preoperatively predicting nodal metastasis is not optimal for guiding lymphadenectomy.

Detecting Recurrent Endometrial Cancer

Endometrial cancer has a low rate of recurrence of 4% to 16% (75). Factors that predict relapse include advanced stage at presentation, high tumor grade, type II histology, age over 60 years, and lymphovascular invasion (91). Following primary surgery, 64% of recurrences occur within 2 years and 87% within 3 years,

FIGURE 11.8. Stage IIIB endometrial carcinoma. Sagittal (A) and axial (B) T2W FSE MR images show an endometrial carcinoma (T in A, B) which invades the cervical stroma (arrow in A) and extends into the right parametrium (arrow in B).

FIGURE 11.9. Recurrent endometrial carcinoma. Axial T2W FSE MR image (A) shows a mass of intermediate signal intensity in the vaginal vault on the right (M in A) in keeping with tumor recurrence from a serous papillary carcinoma of the endometrium. CT image (B) of the same patient shows a peritoneal deposit (arrow in B) in the right paracolic gutter.

the most common sites being lymph nodes (46%) and the vaginal vault (42%) (92). Less frequently, recurrent disease may manifest as peritoneal carcinomatosis (28%) or distant metastases in liver, lung, or bone (92). Routine follow-up has a poor yield in detecting recurrence in the asymptomatic patient, but recognizing those patients who are at an increased risk of recurrence and the likely time scale for recurrence can help in selecting a suitable approach for follow-up imaging.

At present, follow-up of patients treated for endometrial cancer usually consists of regular clinical evaluation. The use of imaging and its impact on the management of these patients is not well defined. CT performs well in the detection of recurrent pelvic and distant metastatic disease (Figs. 11.9 and 11.10), with an overall accuracy of 92% (93). MRI has a role in the evaluation of surgical resectability, if the pelvis is the sole site of recurrence. On T2WI, vaginal vault recurrence is seen as loss of the linear, low signal intensity of the vaginal vault and an associated soft tissue mass of high signal intensity, similar to that of the primary tumor (Fig. 11.9). FDG-PET/CT is helpful in assessing patients with suspected disease recurrence within the pelvis, by detecting

unsuspected distant metastases, the presence of which significantly alters treatment options (94,95). A recent study compared PET integrated with low-dose, unenhanced CT to PET integrated with contrast-enhanced CT (95). It concluded that PET with contrast-enhanced CT is an accurate imaging modality for the assessment of endometrial cancer recurrence and the use of contrast reduces the frequency of equivocal interpretations (95). FDG-PET/CT resulted in a change of management in 42% of patients (95). PET is reportedly useful in posttherapy evaluation and surveillance of patients with suspected recurrence, but it does not have any proven value in asymptomatic patients (96,97).

UTERINE SARCOMA

Uterine sarcomas are rare, aggressive tumors of mesenchymal origin that account for 2% to 3% of all uterine malignancies. They differ from endometrial carcinomas with regard to their

FIGURE 11.10. Recurrent endometrial carcinoma. Axial contrast-enhanced CT images through the lower chest (A) and pelvis (B) demonstrate lung nodules (white arrows in A) and a soft tissue mass with osseous destruction (white arrow in B), both proven to be recurrent endometrial cancer.

clinical behavior, pattern of spread, and management. Although there are no specific imaging findings for uterine sarcomas, imaging (MRI) can be useful to make a correct preoperative diagnosis and evaluate the extent of disease (CT). On MRI, cases that arise within the endometrium may be indistinguishable from endometrial carcinoma, whereas those that arise from the myometrium, usually leiomyosarcomas, may be indistinguishable from degenerating leiomyomas. However, if there are features suggesting the diagnosis preoperatively, alerting the surgeon can alter management by changing the extent of primary surgery or by indicating that surgical management is preferable to embolization or high-intensity focused US. CT can be a very helpful adjunct for detection of distant metastatic disease (usually in the lungs) and recurrence.

Uterine sarcomas are divided into three main subtypes: carcinosarcoma, endometrial stromal sarcoma (ESS), and leiomyosarcoma (LMS). Carcinosarcoma accounts for approximately 50% of all uterine sarcomas (98) and can arise anywhere along the Müllerian axis. Risk factors include a previous history of radiotherapy for an unrelated pelvic malignancy and long-term tamoxifen use (99,100). Carcinosarcomas do not have a pathognomonic appearance on MRI and may be indistinguishable from endometrial carcinomas (101,102). However, when compared with endometrial carcinoma of a similar size, carcinosarcomas are heterogeneous tumors with areas of hemorrhage and necrosis, and enhance more avidly than the adjacent normal myometrium. They demonstrate deep myometrial invasion, cervical stromal invasion, and metastatic nodal disease (101,103,104) more often than do endometrial carcinomas and hence have a poorer prognosis (105-107).

ESS accounts for 10% of primary uterine sarcomas (98). It can be subdivided into low- and high-grade categories, which have distinctly different presentations and outcomes (108). A preoperative diagnosis of high-grade ESS is readily established at histopathology whereas low-grade ESS may be difficult to distinguish from benign endometrial stromal cells in a small sample obtained at curettage. As low-grade ESS usually occurs in young women in whom malignancy is not suspected, the role of MRI is important in providing a clue for preoperative diagnosis.

On MRI, ESS commonly appears as a polypoid mass of homogeneous high signal intensity on T2WI, although areas of necrosis or hemorrhage may also be seen (102,108). The low-grade ESS may be a mimicker of adenomyosis; however, the presence of multiple intra-tumoral flow voids due to neovascularity, multiple marginal tumor nodules, continuous tumor extension along vessels, ligaments, and fallopian tubes due to

marked vascular and lymphatic invasion, with separate myometrial tumor nodules within invaded vessels, are highly suggestive of ESS (102,108,109). Intravenous leiomyomatosis is also in the differential diagnosis if there is involvement of periuterine vessels.

LMS account for approximately one-third of primary uterine sarcomas (98). Most arise *de novo*, but they may rarely (0.2%) result from sarcomatous transformation within a benign leiomyoma. On MRI, in contrast to benign leiomyomas, which have a well-defined margin, LMS are usually irregular and ill-defined. They commonly cause massive uterine enlargement with areas of heterogeneous enhancement, extensive necrosis (>50%) and hemorrhage as well as extrauterine tumor nodules (Fig. 11.11) (102). LMS demonstrate early hematogenous spread to the lungs and liver. Although MRI cannot reliably differentiate most cases of sarcomatous transformation of a leiomyoma from a benign degenerating leiomyoma, features most suggestive of sarcomatous transformation include irregular margins, necrosis, and rapid growth.

GESTATIONAL TROPHOBLASTIC DISEASE

Introduction

Gestational trophoblastic disease (GTD) encompasses a spectrum of placental lesions including hydatidiform mole, invasive mole, choriocarcinoma, and placental site trophoblastic tumor. The role of imaging in GTD is to distinguish benign disease from retained products of conception, and to document metastatic disease or to evaluate for persistent disease. No specific imaging findings allow differentiation between the different GTD lesions (110-112).

Primary Detection, Characterization, Staging, and Monitoring for Recurrence of Gestational Trophoblastic Disease

Ultrasound

TVS is considered the study of choice in the evaluation of suspected GTD. In patients with GTD, TVS examination most commonly demonstrates a soft-tissue mass distending the

FIGURE 11.11. Leiomyosarcoma. Sagittal T2W FSE (A) and axial gadolinium-enhanced 3D T1W GRE (B) MRI images show an enlarged heterogeneous uterus (T in A, B) with areas of necrosis in keeping with a leiomyosarcoma.

FIGURE 11.12. Hydatidiform mole. Gray scale sagittal ultrasound image of the uterus (A) demonstrates an echogenic, heterogeneous mass within the endometrial canal (white arrows in A). Axial contrast-enhanced CT image (B) in the same patient demonstrates enhancing soft-tissue distending the endometrial canal (white arrow in B). Gray scale ultrasound image (C) of the right ovary and contrast-enhanced CT image (D) through the pelvis in the same patient demonstrate bilateral enlarged ovaries with innumerable theca lutein cysts (white arrows in C, D).

endometrial cavity. Typically, the mass is echogenic and heterogeneous, containing numerous cystic spaces (Fig. 11.12) (110,113, 114). In the case of complete hydatidiform mole, the small cystic spaces correspond to the hydropic villi (110). Hydropic degeneration of the placenta may have a similar US appearance. The mass is usually extremely vascular, demonstrating increased vessel density and an abnormal uterine arterial waveform characterized by high peak systolic velocity and high diastolic blood flow (low resistance index [RI]) compared to the normal uterine arterial waveform (115). Irregularity of the border of the mass or asymmetric extension of the mass into the myometrium suggests myometrial invasion.

The ovaries may become enlarged with numerous theca lutein cysts (Fig. 11.12). This ovarian enlargement can result in symptomatic ovarian torsion or hemorrhage (116). However, theca lutein cysts may not be detected in the early stages of the disease (114).

US can be helpful in assessing for persistent or recurrent disease by documenting an endometrial mass (117). GTD is the most common cause of uterine vascular malformations. These vascular malformations usually present after treatment is complete and can be easily diagnosed with US. They can be treated with uterine artery embolization under fluoroscopic guidance (118).

Computed Tomography

The role of CT in the evaluation of GTD is primarily limited to the detection of metastatic disease. Uterine enlargement is the most common CT feature of GTD. Following administration of intravenous contrast, uterine enhancement is typically heterogeneous with focal enlargement or irregular hypodense regions within the myometrium (Fig. 11.12) (116). These low-attenuation areas correspond to foci of hemorrhage and/or necrosis (116). Contrast-enhanced CT often demonstrates vascular uterine lesions and dilated uterine vessels in the broad ligaments (116).

Locoregional spread is characterized by avidly enhancing soft-tissue nodules in the parametria and/or obliteration of the pelvic fat and/or muscle planes. GTD spreads hematogenously, with the lungs being the most common site of metastatic disease. Metastases to the lung, liver, and brain are vascular and prone to hemorrhage (116). CT detects these metastatic lesions in the usual manner. Trophoblastic emboli to the lungs may produce symptoms of acute pulmonary embolism and occasionally result in large intravascular masses (116).

Magnetic Resonance Imaging

MRI is primarily used for staging and detecting recurrent disease. On T2WI, GTD is seen as a heterogeneous, predominantly

high signal intensity mass that obliterates the normal uterine zonal anatomy (Fig. 11.13) (119). On T1WI, the mass may be isointense or hyperintense compared to the adjacent normal myometrium. The tumors are hypervascular, and enlarged vessels in the broad ligament and the uterus are depicted as signal voids on both T1W and T2WI. Following gadolinium contrast administration, the tumors avidly enhance, and multiple enlarged vessels are often seen. MRI is able to depict tumors that invade the myometrium but spare the endometrium, a cause of nondiagnostic and/or false-negative D&Cs.

MRI is also useful in the identification of extrauterine pelvic spread to the parametria, adnexa, and vaginal fornices (119). Parametrial involvement is seen on MRI as high T2W signal masses within the parametria that avidly enhance after gadolinium contrast. MRI is better at detecting parametrial involvement than US. MRI is the preferred method for determining vaginal spread of tumor. Vaginal involvement is identified on MRI as a high-T2W-signal-intensity mass within the vagina with associated gadolinium contrast enhancement. Metastatic disease is usually hypervascular and is detected in the usual manner.

Another role of MRI is to monitor patient's response to therapy. MRI findings of regression of vascular abnormalities, development of intralesional hemorrhage, and return of normal uterine zonal anatomy parallel a favorable response to chemotherapy (119). Normal uterine zonal anatomy should be seen 6 to 9 months after treatment (119).

Positron Emission Tomography/Computed Tomography

The very limited data available on the use of FDG-PET in patients with GTD show that FDG-PET may be helpful in the detection of metastatic disease and recurrent disease. One study found that FDG-PET might be useful in the detection of metastatic disease (120). Another study demonstrated that FDG-PET/CT was helpful in 43.8% of patients when compared with CT alone (121). More research into the use of FDG-PET is needed before the clinical utility of this modality for evaluation of GTD can be established.

CERVICAL CANCER

Introduction

The role of imaging in patients with cervical cancer includes evaluation of extent of disease, monitoring treatment response, and detecting tumor recurrence. MRI is the modality of choice for evaluating disease extent and monitoring treatment response; CT and PET/CT are utilized in the evaluation of distant metastatic disease or when MRI is contraindicated. CT, MRI, and PET/CT are useful in the evaluation of recurrent disease.

Primary Detection and Characterization of Cervical Cancer

Cervical cancer is usually detected at Pap smear test or by physical examination. Imaging plays no role in the detection and characterization of cervical cancer.

Staging Cervical Cancer

FIGO classification is the most widely used staging system for cervical carcinoma (63,122). FIGO staging of cervical carcinoma is clinical and does not rely on surgico-pathological findings.

FIGURE 11.13. Partial mole. Sagittal (A) and axial (B) T2W FSE MR images demonstrate a heterogeneous mass within the uterus (white arrows). Fetal abdomen (black arrow in A) and umbilical cord (black arrow in B) can be seen adjacent to the mass.

Thus, it allows uniformity of staging for all patients worldwide; this is particularly important because cervical carcinoma is most prevalent in countries where surgical and diagnostic resources are limited.

Clinical staging of cervical cancer has inherent deficiencies in evaluating several important prognostic factors including

tumor size, parametrial and pelvic sidewall invasion, and nodal metastasis. When compared with surgical staging, clinical FIGO staging can be erroneous in up to 32% of patients with stage IB disease and up to 65% of patients with stage III disease (123,124). This is problematic, as accurate pretreatment evaluation of these prognostic factors determines the appropriate choice of initial treatment for ensuring the best possible patient outcome.

There are two standard primary treatment options for cervical cancer: (a) radical surgery in early-stage disease (IA, IB1 and IIA1) or (b) primary radical radiotherapy with concurrent administration of platinum-based chemotherapy for patients with bulky IB2/IIA2 disease (tumors larger than 4 cm) or locally advanced disease (stage IIB or greater). Therefore, the FIGO staging committee has acknowledged that clinical staging errors occur with reasonable frequency and the 2009 revision has, for the first time, encouraged the incorporation of cross-sectional imaging techniques (MRI/CT) into the evaluation and treatment planning of patients with cervical cancer, where available (63,122).

Ultrasound

Transabdominal sonography plays a limited role in the staging of cervical cancer and is inferior to other cross-sectional modalities in this role. Although the improved spatial resolution achieved with TVS and TRUS is helpful in the evaluation of tumor size and locoregional extent, poor soft-tissue contrast impedes differentiation between tumor and normal adjacent cervical, uterine, parametrial, and vaginal tissue (125). In addition to the limited soft-tissue contrast offered by US, the small field of view leads to suboptimal evaluation of parametrial invasion. Therefore, US plays no significant role in staging of patients with cervical cancer.

Computed Tomography

CT is often used for the staging of advanced cervical carcinoma (Fig. 11.14) because of its large field of view, widespread availability, and large numbers of experienced readers. However, CT has many limitations including poor detection of small primary tumors, parametrial invasion, and early invasion of the rectum and bladder mucosa. A prospective multicenter study conducted jointly by the American College of Radiology Imaging Network (ACRIN) and the Gynecologic Oncology Group (GOG)

compared MRI, CT, and FIGO clinical staging in the pretreatment assessment of early invasive cervical cancer (126,127). The study found that MRI was equivalent to CT for overall preoperative staging. However, MRI performed significantly better than CT for tumor visualization (127) and determination of parametrial invasion (128). Reader agreement was higher for MRI than for CT (126). In this study, the sensitivity, specificity, and negative predictive value (NPV) of CT in staging cervical carcinoma of stage IIB or greater were 42%, 82%, and 84%, respectively (126). Despite its limitations, CT is a valuable complement to clinical staging because of its accuracy in detecting advanced disease (129,130).

Magnetic Resonance Imaging

MRI is considered the best single imaging study for cervical cancer and can accurately determine tumor location (exophytic or endocervical) and size; presence of invasion into the parametria, pelvic sidewall, or adjacent organs; and the presence of nodal enlargement (131,132). Clinical evaluation of tumor size is inaccurate, reported to be as low as 60%, as it may underestimate tumors with an endophytic component (131,132). Conversely, MRI is very accurate for the evaluation of tumor size, providing estimates within 5 mm of the histological size in 93% of cases (133,134). This is particularly important in young women with small-volume invasive disease who wish to preserve fertility, in whom a more conservative surgical procedure can be performed; this involves resection of the cervix together with 2 cm of the parametrium (radical trachelectomy) and lymphadenectomy (135–137). MRI is mandatory in order to determine eligibility for fertility-sparing surgery in terms of tumor size (<2 cm), cervical length (>2.5 cm), distance of tumor from the internal cervical os (>1 cm), and presence of deep cervical stromal invasion (136,137).

Clinical assessment of parametrial and pelvic sidewall invasion is also problematic, with reported accuracy of 29% to 53% (133,138). While an experienced clinician can usually detect gross parametrial invasion, early invasion invariably goes undetected. MRI is very accurate (accuracy of 88% to 97%, specificity of 93%) in evaluating parametrial invasion (25,139). The high NPV (94%) of MRI in excluding parametrial invasion is important clinically, allowing correct selection of patients suitable for radical surgery (134,137,140,141). MRI has also been shown to have a very high NPV (up to

FIGURE 11.14. Stage IVA cervical carcinoma. Contrast-enhanced CT images at two levels (A, B) demonstrate a heterogeneous mass arising in the cervix (black asterisk) with extension into the uterus (white arrow in A) and bladder (black arrow in B). Note the loss of the normal periureteral fat plane around the left ureter (white arrow in B).

100%) for excluding bladder and rectal invasion, thereby negating the need for cystoscopic or endoscopic staging procedures (17,128,142).

MRI is highly accurate for detecting nodal enlargement, which is crucial for treatment planning (143,144). Surgically treated stages IB and IIA survival rates decrease from 85%–90% to 50%–55%, respectively, in the presence of pelvic nodal metastases (141). Although FIGO staging does not include surgical lymph node assessment (122), nodal metastases are an important factor in the choice of adjuvant radiotherapy. Surgical lymphadenectomy is the gold standard in the diagnosis of nodal metastases, but it carries a risk of complications. Therefore, preoperative assessment of nodes with imaging is important (145). Finally, MRI is also routinely used in monitoring treatment response, detection of recurrence, identifying complications of the disease and its treatment (146), and planning radiotherapy (147,148).

Criteria for MRI Interpretation According to Tumor Stage

MRI is complementary to clinical assessment in staging cervical carcinomas of FIGO stage IB1 or greater. In single-institution studies, MRI has been shown to be better than either CT or physical examination in demonstrating parametrial invasion. The staging accuracy of MRI ranges from 85% to 96% (132,139,149). Recommendations for diagnostic evaluation of tumor staging are derived from the FIGO clinical staging system (Table 11.3).

Stage I tumors are confined to the cervix. In stage IA, disease is microinvasive and cannot be seen on MRI. Stage IB is defined as clinically visible tumor limited to the cervix and is subdivided by size into IB1 (<4 cm in greatest dimension) (Fig. 11.15) and IB2 (>4 cm in greatest dimension). The tumor appears as intermediate signal intensity mass in contrast to the low signal intensity cervical stroma on T2WI (132).

Table 11.3 FIGO Staging of Cervical Carcinoma with Corresponding MR Findings

FIGO Stage	Description of Stage	MRI findings
Stage I	The carcinoma is strictly confined to the cervix	
IA	Invasive carcinoma which can be diagnosed only by microscopy, with deepest invasion <5 mm and largest extension >7 mm	MRI is not indicated in stage IA as tumor not seen (except cases considered for fertility-sparing surgery such as trachelectomy)
IA1	Measured stromal invasion of <3 mm in depth and extension <7 mm	
IA2	Measured stromal invasion of >3 mm and not >5 mm with an extension of not >7 mm	
IB	Clinically visible lesions limited to the cervix uteri or preclinical cancers greater than stage 1A	Mass of intermediate signal intensity on T2WI. MRI can accurately delineate the tumor and its location and provide accurate size measurement (including distance from the internal os and cervical length in cases considered for trachelectomy)
IB1	Clinically visible lesions <4 cm in greatest dimension	
IB2	Clinically visible lesions >4 cm in greatest dimension	
Stage II	Cervical carcinoma invades beyond the uterus, but not to the pelvic wall or to the lower third of the vagina	Accurate evaluation of tumor location and tumor size. Invasion of the upper two-third of vagina is indicated by disruption of the low SI vaginal wall by high SI tumor on T2WI
IIA	Without parametrial invasion	
IIA1	Clinically visible lesion <4 cm in greatest dimension	
IIA2	Clinically visible lesion >4 cm in greatest dimension	
IIB	With obvious parametrial invasion	Parametrial invasion is indicated by disruption of the low SI stromal ring and presence of a spiculated tumor/parametrium interface, gross nodular tumor extension into the parametrium, or encasement of the uterine vessels by tumor
Stage III	The tumor extends to the pelvic wall and/or involves the lower third of the vagina and/or causes hydronephrosis or nonfunctioning kidney	
IIIA	Tumor involves lower third vagina, no extension to pelvic wall	Invasion of the lower one-third of vagina is indicated by disruption of the low SI vaginal wall by high SI tumor on T2WI
IIIB	Extension to the pelvic wall and/or hydronephrosis/nonfunctioning kidney	Pelvic sidewall invasion is indicated by tumor extension within 3 mm of pelvic sidewall. Hydronephrosis is an indication of ureteral and/or bladder invasion
Stage IV	The carcinoma has extended beyond the true pelvis or has involved (biopsy proven) the mucosa of the bladder or rectum	Bladder or rectal invasion is indicated by loss of perivesical/perirectal fat planes and disruption of the normal low signal intensity bladder/rectal mucosa. Note that bullous edema doesn't indicate stage IVA
IVA	Spread to adjacent organs	
IVB	Distant metastases (including intra-abdominal metastases) and/or inguinal lymph nodes	Tumor in distant sites or organs

FIGURE 11.15. Stage IB1 cervical carcinoma. Sagittal (A) and axial oblique (B) T2W FSE MR images show a cervical cancer measuring < 4 cm (T in A, B). The low signal intensity cervical stroma is intact (arrows in B) confidently excluding presence of parametrial invasion. Histopathology confirmed a stage IB1 squamous carcinoma of the cervix.

Stage II is defined as tumor growth beyond the cervix but without extension to the pelvic sidewall or the lower third of the vagina. In stage IIA, there is invasion of the upper two-thirds of the vagina without parametrial invasion. Segmental disruption of the hypointense vaginal wall is demonstrated on T2WI. Stage IIA is again subdivided by size into stage IIA1 (<4 cm in greatest dimension) and stage IIA2 (>4 cm in greatest dimension); this subdivision reflects a difference in prognosis similar to that observed between stages IB1 and IB2, which is in turn reflected in differing treatment strategies (122). On MRI, stage IIB disease is seen as disruption of the low signal intensity stromal ring on T2WI; a spiculated tumor to parametrium interface, overt soft tissue extension into the parametria (Fig. 11.16) and encasement of the peri-uterine vessels are additional signs of stage IIB that enhance diagnostic confidence (131). If the intact peripheral low signal intensity stromal rim of the cervix is greater than 3 mm (“hypointense rim sign”), parametrial invasion can almost be excluded with specificity of 96% to 99% and NPV of 94% to 100% (25,138,139). An important pitfall is the overestimation of parametrial invasion on T2WI with large tumors (accuracy of 70%) compared to smaller tumors (accuracy 96%) (132,138,141). Large tumors can cause stromal edema, from

tumor compression or inflammation, which can obscure the real tumor boundary. False positive parametrial invasion can also occur due to postbiopsy hemorrhage. These factors must be considered when making treatment decisions (138,141).

Stage III cervical cancer is defined as tumor extension into the lower third of the vagina and/or pelvic sidewall. In stage IIIA, there is invasion of the lower third of the vagina without extension to the pelvic sidewall. When the tumor extends to the pelvic sidewall or causes hydronephrosis, it is stage IIIB. Tumor visualized within 3 mm of the obturator internus, levator ani, and piriformis muscles or the iliac vessels is suggestive of stage IIIB disease (138).

Stage IV indicates adjacent organ invasion and/or distant metastatic disease. Disruption of low signal intensity bladder mucosa (Fig. 11.17) or rectal wall by high signal intensity tumor on T2WI with tumor involving the mucosa constitutes stage IVA disease. Direct invasion of the rectum is uncommon, as the Pouch of Douglas separates the posterior fornix from the rectum, making the uterosacral ligaments the preferred route for rectal invasion. By adopting a low threshold for invasion, the absence of bladder or rectal invasion can be diagnosed with sufficient confidence using MRI (NPV = 100%) to safely obviate

FIGURE 11.16. Stage IIB cervical carcinoma. Sagittal (A) and axial oblique (B) T2W FSE MR images show a large cervical cancer (T in A, B). On the axial oblique image there is a spiculated tumor to parametrium interface on the right and a tumor nodule present in the left parametrium in keeping with bilateral parametrial invasion (arrows in B).

FIGURE 11.17. Stage IVA cervical carcinoma. Sagittal (A) and axial oblique (B) T2V FSE MR images show a large cervical cancer (T in A, B) that invades the cervical stroma and extends into both parametria as indicated by a spiculated tumor to parametrium interface. Tumor also invades the bladder mucosa (black arrows in A, B) and both distal ureters (white arrows in B) causing bilateral hydronephrosis.

the need for invasive cystoscopic or endoscopic staging in the majority of patients with cervical cancer (142). In stage IVB, distant metastatic disease is present.

Positron Emission Tomography/Computed Tomography

FDG-PET is useful in staging patients with advanced cervical cancer, especially in the detection of lymph node metastases (Fig. 11.18). Although lymphadenopathy is not part of the FIGO staging system, it is considered stage IVB disease and knowledge of its presence is therefore crucial when developing a treatment plan. Conventional cross-sectional imaging modalities rely on size criteria for the diagnosis of lymphadenopathy, and, therefore, microscopic disease often goes undetected. FDG-PET is better than the conventional imaging modalities in the detection of lymphadenopathy in patients with cervical cancer, with sensitivities of 75% to 100% and specificities of 87% to 100% (150–153). Reinhardt et al. (154) found that in the detection of involved lymph nodes, sensitivity, specificity, and positive predictive value (PPV) were 91%, 100%, and 100%, respectively, for FDG-PET, as compared to 73%, 83%, and 67%, respectively, for MRI. Another study demonstrated that the accuracy of FDG-PET in the detection of lymph node metastasis was 88%, compared to 75% with MRI (155). FDG-PET also improves initial staging in cases of advanced disease by demonstrating unexpected sites of disease beyond the pelvis or retroperitoneum, such as supraclavicular nodal metastases (156). PET or PET/CT has been found to alter management in a significant number of patients with advanced disease (FIGO IIB–IVB) at presentation (157). In contrast, the value of FDG-PET in early-stage disease (FIGO I to IIA) is questionable. Many studies have reported low sensitivities for the detection of nodal metastases, ranging from 25% to 73%. Chao et al. concluded that PET/CT has a limited role in staging for patients with early-stage disease and should not replace lymphadenectomy for the detection of lymph node metastases (157).

FDG-PET has prognostic value in patients with cervical cancer (158). Kidd et al. found that the maximum SUV (SUV_{max}) of the primary cervical tumor at diagnosis was a sensitive biomarker of treatment response and prognosis for patients with cervical cancer (159). Recently, the same group (160) reported that the SUV_{max} of pelvic lymph nodes is a prognostic

biomarker, predicting treatment response, pelvic recurrence risk, and disease-specific survival in patients with cervical cancer. Increasingly, FDG-PET/CT is being advocated to aid delivery of intensity-modulated radiation therapy (IMRT) (161,162). In a study on 452 patients treated with curative intent (135 with IMRT) based on FDG-PET/CT, the IMRT group showed better overall survival, although recurrence-free survival did not reach statistical significance (161).

Monitoring Treatment Response and Detecting Recurrent Cervical Cancer

Recurrent cervical cancer typically occurs early in the course of disease (60% to 70% percent of cases occur within two years of starting treatment) (163). Salvage treatment may prolong survival, particularly when the recurrence is detected at an early stage. Location of the recurrent disease and initial therapy will determine the course for subsequent treatment. Recurrent disease restricted to the vaginal vault or pelvic sidewalls may be treated with chemoradiotherapy, if this has not been given previously. Patients previously treated with chemoradiotherapy who develop central recurrence may be suitable for pelvic exenteration. Distant metastatic disease may be treated with chemotherapy, and the patient may be offered clinical trial entry. It is imperative to accurately identify those patients deemed suitable for such radical steps as pelvic exenteration, which is associated with considerable morbidity (164). There is, however, no consensus regarding routine follow-up imaging. Imaging is only undertaken if indicated by clinical symptoms or signs, or in cases treated with fertility-preserving radical trachelectomy.

Ultrasound

Currently, there is no role for US in the evaluation of cervical cancer response to chemoradiotherapy or in the detection of recurrent disease.

Computed Tomography

CT is useful for the detection of tumor recurrence in the pelvis following hysterectomy as well as the assessment of metastases

FIGURE 11.18. Stage IIB cervical carcinoma. Axial oblique T2W FSE MR (A), unenhanced CT (B), FDG-PET (C), fused PET/CT (D), and coronal MIP images show a large cervical tumor (*T* in A-D) with invasion into the left parametrium. A metabolically active perirectal lymph node is present (*arrow* in A-D), as well as bilateral external iliac lymphadenopathy (*arrows* in E).

to the peritoneum and solid organs (particularly the liver, lungs, and adrenal glands) (93), but it has limited value for detecting recurrent tumor after chemoradiotherapy, because of poor soft-tissue contrast between the recurrent tumor and the irradiated cervix (93,130). CT features of recurrent pelvic tumor include

soft-tissue asymmetry, soft-tissue mass, compression and invasion of adjacent organs, tumor extension to the pelvic sidewall, and hydronephrosis (165). Pelvic and paraaortic nodal metastases are also often present in patients with recurrent disease and are well depicted by CT (93).

Magnetic Resonance Imaging

In patients treated with primary chemoradiotherapy, MRI is routinely used to monitor response during and at the completion of treatment (29). Change in tumor size on sequential MRI is the standard method for evaluating response to chemoradiotherapy in patients with advanced cervical carcinoma. Decrease in tumor volume can be seen as early as 2 months after treatment and predicts a good prognosis (166). The reconstitution of the normal low signal intensity cervical stroma is the most reliable indicator of a tumor-free postradiation cervix (167,168). If a small area of residual tumor is detected at the completion of treatment, there is a window of opportunity to offer exenterative surgery. These patients should undergo FDG-PET/CT before surgery to exclude distant spread of disease. If, after chemoradiation, the patient is found to have a complete response, no further routine imaging is required.

Physiological imaging with DW-MRI and DCE-MRI are complementary to standard morphological response assessment by MRI. Pretreatment DCE-MRI parameters can predict response to chemoradiotherapy and may enable alteration of treatment strategy in patients with advanced cervical cancer (169–172). DW-MRI has the potential to be used as a response biomarker, to provide a surrogate end-point in the assessment of treatment response in advanced cervical cancers. Measurement of ADC values has been shown to have potential for monitoring early response to chemoradiotherapy (173–176).

MRI plays an important role in evaluation of recurrent cervical cancer. It is useful in the evaluation of surgical resectability, if the

pelvis is the sole site of recurrence. On T2WI, vaginal vault recurrence is seen as loss of the linear, low signal intensity of the vaginal vault and an associated soft tissue mass of high signal intensity, similar to that of the primary tumor. MRI is superior to CT in distinguishing radiation fibrosis from recurrent disease. On MRI, tumor recurrence appears as a region of intermediate to high signal intensity on T2WI compared to the low signal intensity irradiated cervix (Fig. 11.19). However, the appearance of recurrence can be indeterminate, particularly within the first six months after treatment (177). In patients with a history of remote radiation therapy (>1 year), the difference in signal intensity between posttreatment fibrosis and recurrent tumor is statistically significant, and a sensitivity of 86% and a specificity of 94% have been reported for detection of recurrent cervical cancer by MRI (178).

Recurrent tumor is more reliably identified on dynamic contrast-enhanced images, as an area showing increased enhancement, than on T2WI (15). The accuracy of dynamic contrast-enhanced MRI for identifying recurrent disease approaches 85% compared to 64% to 68% for unenhanced T2W images (15,179). On DW-MRI, hyperintense signal on high-b-value images associated with lower ADC values suggests active tumor (180).

Positron Emission Tomography/Computed Tomography

In patients with cervical cancer, there is a role for FDG-PET in treatment response assessment, where findings of residual

FIGURE 11.19. Recurrent cervical carcinoma. Axial oblique T2W FSE MR (A), unenhanced CT (B), FDG-PET (C), and fused PET/CT (D) images show cervical cancer recurrence in the vaginal vault (T in A–D).

metabolically active disease, 3 months after completion of treatment, may be used to guide additional therapy (181).

PET/CT plays an important role in the management of patients with suspected recurrent cervical cancer. In this context, the applications of PET/CT include detection of recurrent disease (Fig. 11.19) at the primary site, assessment of nodal disease, and detection of distant metastases and radiotherapy field planning (88,182). FDG-PET/CT is increasingly used in identifying pelvic recurrence with sensitivity, specificity, and accuracy of 92.0%, 92.6%, and 92.3%, respectively (183). In addition to local recurrence, FDG-PET/CT is able to detect peritoneal dissemination, paraaortic lymph node metastasis, pelvic lymph node metastasis, and lung metastases. Mittra et al. showed that posttreatment surveillance with PET/CT is highly effective in identifying both residual/recurrent disease and distant metastases. All 30 patients in the study had a change in their management on the basis of the PET/CT findings (184). Similarly, Pallardy et al. found that the use of FDG-PET/CT in patients suspected cervical cancer recurrence modified treatment in more than 50% of patients with negative conventional imaging (185).

FDG-PET/CT is also promising in asymptomatic patients. In a series of 103 patients, FDG-PET/CT detected recurrence in nine of 78 (11.5%) asymptomatic patients and 21 of 25 symptomatic patients at 13 months (186). In 100 women, a study examining the use of unenhanced versus contrast-enhanced CT with integrated FDG-PET/CT showed no significant difference in sensitivity or specificity for detecting recurrence, although the latter was helpful in correctly interpreting a few equivocal findings on unenhanced CT (95).

OVARIAN CANCER

Introduction

The detection of early ovarian cancer is difficult for a variety of reasons and currently involves a combination of physical examination, CA-125 levels, and TVS. At present, there is no screening strategy that reliably detects early ovarian cancer. Because of this, ovarian cancer is often not diagnosed until it has spread to other organs. Imaging by means of US, CT, MRI, and FDG-PET/CT plays a crucial role in detection, characterization, staging, and follow-up of patients with ovarian cancer.

Primary Detection and Characterization of Ovarian Cancer

The 5-year survival rates for stage I and stage II ovarian cancer are 90% and 70%, respectively (187,188); however, the 5-year survival rate for stages III and IV ranges from 5% to 30% (188). Therefore, if more ovarian cancers were detected as stage I disease rather than stage III or IV disease, 5-year survival would dramatically improve. Unfortunately, there are no good screening methods for ovarian cancer at present; most use a combination of physical examination, CA-125 levels, and TVS.

Ultrasound

US plays a crucial role in the detection and characterization of adnexal masses, and is an important component of screening programs for women at high risk for ovarian carcinoma. US is the initial imaging modality of choice for characterization of ovarian masses.

The early diagnosis of ovarian carcinoma, when cure is possible but tumors are clinically asymptomatic (silent), is made difficult by the low prevalence of ovarian carcinoma in the

general population. Therefore, efforts at screening patients for ovarian carcinoma have focused on high-risk populations. Risk factors include older age, high socioeconomic status, factors that increase the number of ovulatory cycles such as early menarche, nulliparity, and late-onset menopause, and having a first-degree relative with ovarian carcinoma (189,190). Approximately 10% of ovarian carcinomas are believed to be due to an inherited susceptibility. Three syndromes have been described: the breast/ovarian cancer syndrome; the Lynch 2 syndrome, or the hereditary nonpolyposis colorectal cancer syndrome; and hereditary site-specific ovarian cancer. In 1994, a National Institutes of Health (NIH) consensus conference (191) recommended that screening be offered to women with two or more first-degree relatives with ovarian carcinoma. It is also recommended that women with an inherited predisposition to ovarian cancer be screened (191–193). In practice, many women with a single first-degree relative are enrolled in screening programs.

Most screening programs for ovarian cancer rely on a combination of physical examination, serologic markers, and TVS. The results of these screening trials have consistently demonstrated that US detects more stage I ovarian carcinomas than CA-125 levels and physical examination (194). Nonetheless, very few stage I carcinomas have been found in such screening programs (195). The data from the Prostate, Lung, Colorectal, and Ovarian (PLCO) Cancer Screening Trial (196) demonstrated that the PPV for invasive cancer was 1.0% for an abnormal TVS, 3.7% for an abnormal CA-125 and 23.5% if both tests (CA-125 and TVS) were abnormal. Only one study has demonstrated ovarian cancer screening trials to have a survival benefit. Van Nagell et al. (197), reported a decrease in case-specific ovarian cancer mortality with 89.9% 2-year and 77.2% 5-year survival in women with US-detected ovarian carcinoma.

Ultrasound is considered as the initial imaging modality of choice to differentiate a benign from a malignant ovarian mass (Fig. 11.20). Although a likely benign mass can be followed or removed by a general gynecologist, suspicion of a malignant ovarian mass initiates referral to a gynecologic oncologist who can better perform the more complex therapeutic and staging cytoreductive surgery for ovarian carcinoma. Morphologic features remain the primary criteria for differentiating complex ovarian masses as benign or malignant on US. Hence, TVS is the critical US imaging approach because of the improved spatial and soft-tissue resolution afforded by the higher frequency endovaginal probe. Nonetheless, transabdominal US remains an important, complementary component of the US examination when a larger field of view is required—for example, if a mass is displaced out of the pelvis or is so large that it is incompletely visualized by TVS. In addition, transabdominal imaging is required for evaluation of secondary findings in ovarian cancer, such as ascites, peritoneal implants, or hydronephrosis. Such findings can be important not only to confirm the impression of malignancy but also for staging.

Numerous studies have reported that when strict US criteria and a pattern recognition approach for identification of benign ovarian masses are used, US examination has a near 95% to 99% NPV in excluding malignancy (198–200). US features consistent with benign etiology include smooth, thin walls; few, thin septations; absence of solid components or mural nodularity; as well as pattern recognition for certain benign diagnoses. Simple cysts will be anechoic with a smooth, thin wall and posterior acoustic enhancement. Endometriomas may contain uniform low-level echoes (Fig. 11.20) but should still demonstrate a smooth, thin wall, increased through transmission. Hemorrhagic cysts may contain complex internal echoes; however, the appearance of the internal echoes should change over time and should never demonstrate internal vascularity. Several US patterns associated with dermoid cysts have been described including uniform increased echogenicity (Fig. 11.20) with or without posterior acoustic attenuation, echogenic mural nodules, and layering with or without floating debris.

FIGURE 11.20. Mature cystic teratoma and endometrioma. Gray scale TVS images (A, B), axial T2W FSE (C), axial T1W (D), and axial T1W FS+ (E) MR images in the same patient. The TVS images demonstrate an echogenic right adnexal mass (D in A) and a left adnexal mass that contains uniform low-level internal echoes (E in B). The right adnexal mass demonstrates high signal intensity on both T1 and T2W images (D in C, D) and loses signal intensity after fat saturation (D in E). These features are in keeping with a mature cystic teratoma. The left adnexal mass demonstrates shading on T2W images (E in C). The mass is of high signal intensity on T1W images before and after fat saturation (E in D, E). The appearances are in keeping with an endometrioma.

Conversely, mural nodules, mural thickening or irregularity (Fig. 11.21), solid components, thick septations (>3 mm), and associated findings such as ascites, peritoneal implants, and/or hydronephrosis, suggest malignancy. Such US descriptors have been reported to have a high sensitivity but lower specificity for malignancy (197,199,200). The lower specificity reflects overlap in the imaging appearance of benign, borderline, and malignant lesions. For example, benign lesions such as hemorrhagic cysts, cystadenomas, or cystadenofibromas may have thick septations and apparent mural nodules; borderline tumors may have minimal findings; and Brenner's tumors, fibromas, and

fibrothecomas are solid but benign. Furthermore, pedunculated fibroids, dermoids, and endometriomas can masquerade as solid ovarian lesions.

The use of color and pulse Doppler in the evaluation of ovarian masses is controversial, with some investigators considering blood flow characteristics to be merely confirmatory, but others considering the Doppler examination to be a helpful discriminator (201–203). Malignant lesions more often demonstrate increased vessel density and tortuosity than benign lesions, but significant overlap exists. Malignant ovarian lesions also tend to demonstrate higher peak systolic velocities and lower

FIGURE 11.21. Ovarian carcinoma. Gray scale TVS image (A) and color Doppler TVS image (B) demonstrate a complex adnexal mass (T in A, B). Note the presence of multiple soft tissue components in the wall of the mass (white arrows in a, b). Increased blood flow is seen in the soft tissue components on the color Doppler image.

resistive indices than benign masses, but again, considerable overlap exists and no discriminatory cut-off values are accepted (201–203).

Scoring systems have been proposed to standardize evaluation of ovarian masses in an attempt to improve specificity (204,205). Using a stepwise logistic regression analysis to determine the most discriminating gray-scale and Doppler sonographic features of malignancy, Brown et al. (204), reported that a multiparameter approach, which assessed for nonhyperechoic solid components, central blood flow on color Doppler, ascites, and thick septations, had 93% sensitivity and specificity for malignancy. To achieve 100% sensitivity, specificity was dropped to 86% in this study (204). However, Timmerman et al. (206) have reported similar results and interobserver variability when readers used subjective criteria for evaluating ovarian masses. Combining Doppler with gray-scale imaging improves the diagnostic assessment of ovarian lesions (Fig. 11.21). A meta-analysis of 46 studies compared the relative utility of gray-scale imaging, color Doppler, and Doppler flow analysis for interrogating adnexal masses, and found that the combination of these methods was more powerful than their individual use (207).

Three-dimensional US may improve characterization of adnexal masses. In one study of 71 pelvic masses, 3-D power Doppler US improved the specificity and PPV compared to conventional 2-D US from 54% to 75% and from 35% to 50%, respectively (208). Contrast-enhanced US has also been used for characterization of adnexal masses. Malignant ovarian lesions show a slower washout of contrast medium than do benign lesions (209–211). The development of diagnostic criteria for the kinetics of contrast enhancement may increase the specificity of US for adnexal malignancies (209).

Computed Tomography

CT is not the study of choice to evaluate a suspected ovarian lesion; however, on CT, ovarian lesions may be detected incidentally and characterized. The sensitivity, specificity, and accuracy of CT for distinguishing benign versus malignant lesions are reported to be 89%, 96% to 99%, and 92% to 94%, respectively (212,213).

On CT, ovarian cancer demonstrates varied morphologic patterns, including a multilocular cyst with thick internal septations and solid mural or septal components (Fig. 11.22), a partially cystic and solid mass, and a lobulated, papillary solid mass (Fig. 11.23). The outer border of the mass may be irregular

and poorly defined, and amorphous, coarse calcifications and contrast enhancement may be seen in the cyst wall or soft-tissue components. In a study of 143 patients with CT and histopathology, features suspicious for malignancy in cystic lesions included multilocularity, irregular wall thickening, and soft tissue nodules, while unilocular homogeneous lesions with thin walls and smooth contours tended to be benign (214). Secondary findings of peritoneal deposits, ascites, and other metastases also aid in distinguishing malignant from benign lesions (Figs. 11.22 and 11.23). Since the CT appearance of ovarian metastases is indistinguishable from a primary ovarian neoplasm, the stomach and colon should be carefully examined as potential primary tumor sites when an ovarian mass is detected on CT (215).

Magnetic Resonance Imaging

MRI is the modality of choice for characterization of adnexal lesions which are indeterminate on US (Fig. 11.20). Ovarian masses at times can grow large, and it can be difficult to determine the organ of origin on US and/or CT. Uterine fibroids and other pelvic masses can also grow to a large size and mimic ovarian tumors. The multiplanar capabilities of MRI are helpful in this situation and often help to delineate the organ of origin of a large pelvic mass and characterize its nature.

It is important to recognize that as there are no MRI signal intensity characteristics that are specific for malignant epithelial tumor; such tumors must be distinguished based on morphologic criteria. Primary and ancillary criteria have been proposed for characterizing an adnexal mass as malignant on MRI. A study of 60 lesions (216) established five primary criteria for malignancy: size greater than 4 cm; solid mass or large solid component; wall thickness greater than 3 mm; septal thickness greater than 3 mm; and/or the presence of vegetations or nodularity and necrosis (Fig. 11.24). Four ancillary criteria of malignancy were also established: involvement of pelvic organs or pelvic sidewall; peritoneal, mesenteric, or omental disease; ascites; and adenopathy. The presence of one or more of the five primary criteria, coupled with a single criterion from the ancillary group, correctly characterized 95% of malignant lesions (216).

Dynamic multiphase contrast-enhanced MRI is useful for the evaluation of adnexal cystic lesions, as it may help differentiate solid components or papillary projections (Fig. 11.24) from clots and debris (32,217). Semiquantitative analysis of enhancement curves shows that early initiation and high rate and magnitude of enhancement are associated with malignancy (32). Dynamic contrast-enhanced MRI (DCE-MRI) can help distinguish among

FIGURE 11.22. Ovarian carcinoma. Axial contrast-enhanced CT images demonstrate bilateral complex cystic and solid adnexal lesions (T in A), omental cake (OC in B), a peritoneal deposit in the gastrohepatic ligament (arrow in C), as well as ascites and bilateral pleural effusions largest on the right (E in D).

FIGURE 11.23. Ovarian carcinoma. Axial contrast-enhanced CT images demonstrate bilateral solid adnexal lesions (T in A), omental cake (OC in B), peritoneal deposits in the pouch of Douglas (PD in A) and subcapsular liver deposits (arrows in B).

FIGURE 11.24. Ovarian carcinoma. Axial T2W FSE (A) and T1W contrast-enhanced fat-saturated (B) MR images show bilateral solid and cystic adnexal masses (T in A, B). Note the avid enhancement of solid components (B) after administration of intravenous gadolinium.

benign, borderline, and invasive tumors. Amplitude and maximal slope of enhancement reportedly achieve 100% sensitivity with 72% and 92% specificity, respectively, in identifying histological invasion (33). A recent study suggested threshold criteria for presence of malignancy; maximum solid tumor enhancement of more than 250 had 100% sensitivity, specificity, and accuracy for prediction of malignancy in preoperative indeterminate adnexal masses (281).

A controversy remains regarding the utility of DW-MRI for differentiating benign from malignant ovarian tumors. Nakayama et al. (219) found no significant difference in ADC values between the benign and malignant cystic ovarian lesions. There was a wide variation in the ADC values of malignant ovarian tumors, which was related to their morphological heterogeneity. Recently, Thomasin-Naggara et al. (220) found that the presence of low-signal-intensity solid components on high-b-value DW images was the most significant criterion for predicting a benign lesion. In their study, all masses that displayed low signal intensity within the solid components on both T2WI and DW-MRI were benign. However, ADC values do not contribute in differentiating benign from malignant adnexal lesions owing to a considerable overlap of mean and lowest ADC values between the two groups (219–221). These findings reflect the histological heterogeneity of ovarian neoplasms, as high ADC values in malignant lesions may arise from desmoplastic stroma, whereas low ADC values in benign lesions, such as fibromas, result from compact cellular organization (220). More recently, the same group reported that the addition of DCE-MRI and DW-MRI to conventional MRI improved diagnostic accuracy in the characterization of complex adnexal masses, allowing accuracy of 95% (222).

Positron Emission Tomography/Computed Tomography

Currently, FDG-PET has little role in the primary detection of ovarian cancer. A study by Hubner et al. (223) found good correlation between FDG-PET and histologic findings in women with suspected ovarian cancer imaged prior to laparotomy. Specifically, the sensitivity, specificity, accuracy, PPV, and NPV of FDG-PET were 83%, 80%, 82%, 86%, and 76%, respectively. A further study found that PET-CT imaging had a sensitivity of 100% and a specificity of 92.5% for the detection of malignant masses (224). Castelluci et al. (225) compared the accuracy of 18F-FDG PET/CT and TVS in distinguishing malignant from benign pelvic lesions in 50 consecutive patients. The sensitivity,

specificity, NPV, PPV, and accuracy of 18F-FDG PET/CT were 87%, 100%, 81%, 100%, and 92%, respectively, compared with 90%, 61%, 78%, 80%, and 80%, respectively, for TVS. The investigators concluded that FDG-PET/CT provided additional value to TVS for the differentiation of benign from malignant pelvic lesions. However, the major pitfall of the study was the lack of comparison with MRI, which remains the modality of choice for characterizing adnexal lesions. Therefore, currently, there is no convincing evidence or justification to suggest the use of PET/CT for characterization of indeterminate adnexal lesions; instead, PET/CT should be reserved for staging and follow-up of patients with ovarian carcinoma.

Staging Ovarian Cancer

The FIGO staging system for ovarian cancer is surgically based. It does not formally include imaging, but the FIGO committee encourages the use of imaging techniques, if available, to assess the important prognostic factors such as disease resectability and lymph node status. The standard of care for patients with newly diagnosed advanced ovarian cancer has been comprehensive staging laparotomy and primary optimal surgical cytoreduction followed by adjuvant chemotherapy (226,227). However, the use of neoadjuvant chemotherapy followed by interval debulking surgery (IDS) as a suitable alternative (228,229) is supported by recent multicenter randomized controlled trials (230,231). Imaging is therefore of paramount importance in helping triage patients for appropriate management by accurately evaluating the extent of anatomical location of peritoneal spread, which in turn dictates the feasibility of cytoreductive surgery and predicts the likelihood of optimal primary cytoreduction. Imaging by US and CT is also used to guide ovarian mass/omental biopsy, which is needed prior to neoadjuvant chemotherapy.

Ultrasound

US has a limited role in the staging of ovarian cancer except in detecting the presence of ascites. Transabdominal US is an excellent modality not only for identifying ascites, but also for guiding paracentesis as well as omental/peritoneal biopsy. However, the detection of stage II and III disease by US is limited. Peritoneal implants can sometimes be documented on careful US examination. The specificity of US examination in documenting abdominal spread of disease has been reported to be slightly

higher than that of CT or MRI (232). However, the sensitivity of US for the detection of implants less than 2 cm (stage IIIB) is lower than that of CT or MRI owing to a limited field of view and decreased spatial and soft-tissue resolution (232,233). US, therefore, should only be used for specific indications.

Computed Tomography

CT is the primary cross-sectional imaging modality used to stage ovarian cancer. It is complimentary to surgical staging identifying possible sites of unsuspected disease, which include the pelvic peritoneum, paraaortic nodes, diaphragm, and chest (234,235). Several clinical studies have demonstrated that the thorax frequently harbors undiagnosed pleural disease at the time of the initial diagnosis, and that this is likely to affect survival even in cases of optimal debulking (236–238). In addition, a recent study found that moderate-to-large pleural effusion on preoperative CT was associated with a decrease in overall survival in patients with stage III or IV ovarian cancer after controlling for age, preoperative CA-125, surgical stage, ascites, and cytoreductive status (239).

Cytoreductive surgery is the treatment of choice for patients with ovarian cancer. “Optimal” cytoreductive surgery (residual disease <1 cm) is a very strong predictor of survival, (240) and even after the threshold for optimal cytoreduction has been reached, it is important to remove as much of the residual tumor as possible (241). Accurate imaging will help guide the surgeon to areas of disease that may be difficult to identify surgically,

and describe the volume and extent of disease for optimal cytoreductive surgery. Relative criteria for “nonoptimally resectable disease” have been developed (242). They include: lymph node enlargement above the renal hilum; presence of abdominal wall invasion; parenchymal liver metastases and subcapsular liver metastases; peritoneal implants of >2 cm along the diaphragm, lesser sac, porta hepatis, intersegmental fissure, and gall bladder fossa; gastrosplenic; gastrohepatic ligament; and small bowel mesentery. However, it is important to realize that these criteria may vary and will depend on the aggressiveness of the surgical procedure and on the performance status of the patient. Therefore, the criteria should only be used as a basis for a multidisciplinary consensus. It is important to note that upper abdominal disease and pleural metastases can be surgically resected, but this requires careful planning as it involves a team of surgeons (e.g., liver surgeons for hepatic resection, and thoracic surgeons for video-assisted thoracoscopic resection of pleural disease).

Criteria for CT Interpretation According to Tumor Stage

CT staging of ovarian cancer should be performed after administration of both intravenous and oral contrast medium, the latter being crucial for detection of tumor deposits along the small and large bowel serosa. Recommendations for diagnostic evaluation of tumor staging are derived from the FIGO surgical staging system (Table 11.4).

Table 11.4 FIGO Staging of Ovarian Carcinoma with Corresponding CT Findings

FIGO Stage	Description of Stage	CT Findings
Stage I	Tumor limited to ovaries (one/both)	
IA	Tumor limited to one ovary, capsule intact, no tumor on ovarian surface, no malignant cells in ascites or peritoneal washings ^a	Enlarged or normal ovary, ascites may be present
IB	Tumor limited to both ovaries, capsule intact, no tumor on ovarian surface, no malignant cells in ascites or peritoneal washings ^b	Enlarged or normal ovaries, ascites may be present
IC	Tumor limited to one or both ovaries with any of the following: capsular rupture, tumor on ovarian surface, malignant cells in ascites or peritoneal washings ^a	Unilateral or bilateral mixed cystic/solid or solid adnexal mass with irregular contour, heterogeneous enhancement of solid components and thick septa. Ascites.
Stage II	Tumor involves one or both ovaries with pelvic extensions or implants	
IIB	Tumor extension and/or implants on uterus/fallopian tube(s), no malignant cells in ascites or peritoneal washings ^a	Irregularity or obliteration of the fat plane between the uterus and the adnexal mass. Dilated fallopian tubes which may contain enhancing soft tissue nodules. Ascites.
IIB	Tumor extension and/or implants on other pelvic tissue, no malignant cells in ascites or peritoneal washings	Loss of the normal fat plane around the rectum or bladder, less than 3 mm between the tumor and the pelvic sidewall, and/or displacement or encasement of the iliac vessels. Ascites.
Stage III	Tumor involves one or both ovaries with microscopically confirmed peritoneal metastasis outside the pelvis.	
IIIA	Microscopically confirmed peritoneal metastasis ^b outside the pelvis (no macroscopic tumor).	Microscopic extra-pelvic peritoneal implants are not detectable with CT
IIIB	Macroscopically peritoneal metastasis outside the pelvis 2 cm or less in dimension.	Omental cake. Peritoneal/serosal deposits <2 cm outside the pelvis.
IIIC	Macroscopically peritoneal metastasis outside the pelvis >2 cm and/or enlarged regional lymph nodes.	Peritoneal implants of >2 cm. Note that subcapsular liver implants and those along the diaphragm, lesser sac, porta hepatis, intersegmental fissure, gall bladder fossa; gastrosplenic, gastrohepatic ligament and small bowel mesentery are “difficult to resect.”
Stage IV	Distant metastasis beyond the peritoneal cavity. Enlarged lymph nodes above the level of the renal hilum	Liver parenchymal metastases, pleural effusion. ^c Enlarged lymph nodes above the level of the renal hilum

^aThe presence of ascites does not affect staging unless malignant cells are present.

^bLiver capsule metastasis are Stage III, liver parenchymal metastasis are stage IV.

^cStage IV: Pleural effusion must have positive cytology.

Stage I ovarian cancer is limited to either one (stage IA) or both (stage IB) ovaries; no tumor is present on the ovarian surface, and no malignant cells in the ascites or peritoneal washings. In stage IC the tumor is still limited to one or both ovaries but there is a capsular rupture, tumor is present on the ovarian surface, and/or malignant cells are present in the ascites or peritoneal washings. Ascites on CT is easily identified; however, the distinction between stage IC and stage III, or subtle peritoneal disease, is often difficult to make out and has significant clinical implications. In one series of patients, the presence of ascites on CT had a PPV of 72% to 80% as a sign of peritoneal metastasis (235).

Stage II disease is characterized by local extension of tumor confined to the pelvis but with no upper abdominal involvement. In stage IIA disease there is extension and/or tumor implants are found in the uterus or fallopian tube(s), but there are no malignant cells in the ascites or peritoneal washings. Stage IIB disease is characterized by extension into and/or implants on other pelvic tissues, with no malignant cells in the ascites or peritoneal washings. Irregularity or obliteration of the fat plane between the uterus and the ovarian mass indicates stage IIA disease. Loss of the normal fat plane around the rectum or bladder, less than 3 mm between the tumor and the pelvic sidewall, and/or displacement or encasement of the iliac vessels, indicates stage IIB disease (243).

Stage III disease is defined as the presence of extra-pelvic peritoneal and/or lymph node metastasis. Microscopic extra-pelvic peritoneal implants are stage IIIA disease and are not detectable with CT. Stage IIIB, extra-pelvic peritoneal implants less than 2 cm and stage IIIC extra-pelvic peritoneal implants larger than 2 cm or lymph node metastasis can easily be detected with CT (Figs. 11.22 and 11.23).

Approximately 70% of patients have peritoneal metastases at staging laparotomy (244). Peritoneal fluid flows from the Pouch of Douglas, along the paracolic gutters to the diaphragm, and hence these are the key areas where peritoneal seeding and deposits occur. There is preferential flow along the right paracolic gutter, and hence the right side of the peritoneum and diaphragm should be especially closely scrutinized on CT for the presence of metastatic disease (245). CT detection of peritoneal implants depends on several factors including location, the presence or absence of surrounding ascites, and size. The three sites most commonly involved are the right subphrenic space, the greater omentum, and the Pouch of Douglas (244). The presence of surrounding ascites aids in the detection of small peritoneal implants by increasing their conspicuity. Size plays an important role in the reliable detection of peritoneal implants. CT has a sensitivity of 14% to 27% for detection of peritoneal implants smaller than 1 cm, especially in the absence of ascites (246,247). However, the use of coronal and sagittal reformatted images improves sensitivity and allows for better detection of smaller lesions (248).

Mesenteric metastases appear as either round or ill-defined soft-tissue masses surrounded by small-bowel loops and mesenteric fat, or as thickened leaves of the mesentery caused by tumor coating the peritoneal surfaces (233). Omental metastases are characterized as stranding or soft tissue nodules embedded in omental fat or the replacement of the omental fat with thick, nodular tumor ("omental cake") along the greater curvature of the stomach, in the gastrosplenic ligament, or anterior to the transverse colon and small bowel in the lower abdomen (249) (Figs. 11.22 and 11.23). The sensitivity of CT for detection of omental metastasis is reported to be 80% to 86% (243,247).

Care must be taken when assessing the liver and spleen. Peritoneal metastasis implanted on the liver surface (liver capsular deposits) is the most common type of liver involvement in ovarian cancer. Sometimes a peritoneal metastasis on the liver surface can invade into the liver parenchyma (subcapsular liver deposits) (Fig. 11.23) (250). Less commonly, direct intrahepatic

metastasis can occur by hematogenous dissemination. Distinction between these different types of liver metastases is important for the selection of an appropriate treatment approach. Perihepatic metastases without parenchymal invasion can be resected directly. However, surgical removal of perihepatic metastases with parenchymal invasion requires liver resection. Information obtained from CT about liver involvement (including involvement of liver regions that are difficult or impossible to explore surgically) is very useful to the gynecologic surgeon, who can obtain appropriate hepatobiliary surgical consultation and necessary equipment in the surgical room. Knowledge of the extent of liver involvement is also important in surgical planning. The presence of multiple perihepatic metastases with parenchymal invasion in multiple regions of both lobes of the liver precludes surgical resection.

Capsular implants on the surface of the liver/spleen are seen as well-defined, biconvex and peripheral soft-tissue nodules studded along the peritoneal surface of the liver. They may indent the liver. Subcapsular liver deposits cause scalloping of the liver surface with an irregular, enhancing interface between the deposit and the liver parenchyma. They can be difficult to differentiate from intraparenchymal liver lesions. The latter are usually less well defined and circular, and partially or completely surrounded by liver tissue (250). Hematogenous spread to the liver can occur in ovarian cancer but it is unusual and should raise the suspicion of a gastrointestinal primary tumor. Tumor extending into the falciform ligament (stage III) can also be mistaken for intraparenchymal disease on axial images, and multiplanar reformatted images can be helpful.

Subcapsular scalloping of the liver can also occur in pseudomyxoma peritonei. This is a rare condition characterized by metastatic thick mucinous or gelatinous material on the surfaces of the peritoneal cavity causing mass effect. Bowel loops are matted posteriorly rather than floating anteriorly and freely within fluid; ascites and fine septae may be visualized. Surgical resection of the insidious mucin is very difficult and repeated laparotomies may be needed (251). Peritoneal mucinous carcinomatosis can arise from mucinous carcinoma of the ovary, gastrointestinal tract, or pancreas with peritoneal spread and is characterized by invasive, high-grade, poorly differentiated mucinous carcinoma with large extracellular pools of mucin. However, it is now widely accepted that the majority of cases of classic pseudomyxoma peritonei develop from low-grade mucinous carcinomas that arise in the appendix, and that penetrate or rupture into the peritoneal cavity (252). Both serous and mucinous cystadenocarcinomas produce unilocular/multilocular fluid-filled masses. Both the primary tumor and the metastatic peritoneal deposits can contain microcalcifications; in serous tumors, these are known as psammoma bodies, and in mucinous tumors they are known as nonpsammoma calcifications. Both types of tumor calcification can be seen on CT (253–255).

Ovarian cancer can also metastasize through the lymphatic system. Lymph node involvement follows the ovarian veins to the paraaortic and aortocaval nodes at the level of the renal hilum; these are the most common sites for metastatic lymphadenopathy. In general, lymph nodes are defined as enlarged if the short axis diameter is greater than 1 cm; pericardiophrenic nodes are an exception, as they are considered suspicious if greater than 5 mm. Tangjitgamol et al. studied 104 ovarian carcinoma patients and demonstrated that the sensitivity for nodal involvement, identified by a nodal size of 1 cm, was 45%, while the specificity was 81%. They concluded that size alone may not reflect nodal disease (256). Lymph vessels also pass through the broad ligament and involve the external iliac, hypogastric, and obturator. Lymph nodes above the renal hilum and those in the inguinal region represent stage IV disease.

There is increasing evidence that primary surgical evaluation of the lymph nodes by extensive systemic lymphadenectomy

at the time of surgical staging is associated with an improved 5-year disease-specific survival rate, even when adjusted for age, stage, grade, and number of positive lymph nodes (257,258). This may be because occult micrometastatic disease that is resistant to chemotherapy is removed (257). However, identifying enlarged lymph nodes preoperatively will guide the surgeon in planning the retroperitoneal dissection.

Stage IV disease is defined by distant metastasis beyond the peritoneal cavity, and it occurs via hematogenous spread. It is the least common mode of tumor spread in ovarian carcinoma but typically occurs in the solid abdominal organs such as the liver, spleen, kidneys, adrenals, brain, and bone. Hematogenous metastases are uncommon at the time of diagnosis. The sensitivity of CT for the detection of extrapelvic disease is approximately 95% to 100% for liver involvement and 50% to 60% for nodal involvement (243,247). Overall staging accuracy for CT has been reported to be 77% (243). CT also has a high PPV for imaging bulky disease and is therefore useful for identifying patients with inoperable disease (243,247).

Magnetic Resonance Imaging

The overall staging accuracy of MRI in patients with ovarian malignancy is 75% to 78% (216,243), which is comparable to that of CT. However, MRI is recommended as a second-line technique for the staging of ovarian cancer, in the pelvis (232,233), where it has some advantages. The main reasons for MRI being used only in selected cases are the long examination time and the technical difficulties in covering a large field of view with adequate resolution. Expertise in interpreting

abdominal MRI, especially in distinguishing peritoneal/serosal deposits from bowel, is limited to specialist centers. Thus MRI is best reserved for problem solving and for staging ovarian cancer in patients for whom CT is contraindicated. The latter include pregnant patients, patients with renal insufficiency, and those with contraindications to contrast media.

Dynamic multiphase contrast-enhanced MRI has high per-lesion sensitivity (95%) and specificity (80%) for detecting peritoneal dissemination (259). Peritoneal/serosal implants and omental cake are best seen on delayed (5 min) images. However, longer delays beyond 5 min should be avoided as ascites may also enhance, impairing visualization of subtle peritoneal implants. Hepatic surface implants are usually well defined, biconvex, and peripheral, and they indent the liver. True intraparenchymal hepatic metastases are often ill-defined, circular, and partially or completely surrounded by liver tissue.

Recently, there has been a growing awareness of the potential of DW-MRI in improving the mapping of the extent of ovarian cancer and quantifying its early treatment response (260–265). The omental cake and peritoneal deposits retain high signal intensity with increasing b values against a background of suppressed signal from surrounding ascites, bowel contents, and fat, increasing conspicuity (260,266) (Fig. 11.25). Fujii et al. showed that DW-MRI is highly sensitive (90%) and specific (96%) in delineating the extent of peritoneal dissemination, with satisfactory interobserver agreement ($\kappa = 0.77$) (260). The combination of DW-MRI and gadolinium-enhanced MRI has been reported to improve the accuracy of tumor detection (accuracy of 84% to 88% compared to 52% to 72% for gadolinium-enhanced MRI alone and 71% to 81% for DW-MRI alone (267). Preliminary

FIGURE 11.25. Ovarian carcinoma. Axial T2W FSE (A), DW (B) and fused (T2WI + DWI) (C) MR images at 3 Tesla demonstrate bilateral solid adnexal masses (T in A, B, C), peritoneal deposits outlining the pelvis (arrows in A, B, C) and serosal deposits along the sigmoid serosa (* in A, B, C).

results also show significantly lower ADC in peritoneal deposits than in primary ovarian tumors and omental cake, suggesting that site-specific diffusion patterns may reflect disease heterogeneity in ovarian cancer (268).

Positron Emission Tomography/Computed Tomography

There is growing evidence that FDG-PET/CT may play a role in preoperative staging of patients with advanced ovarian cancer. FDG-PET/CT can lead to stage migration (269). This is an important finding, as accurate pretreatment staging is one of the determinants of the amount of residual tumor after primary surgery, which is the strongest predictor of patient outcome.

FDG PET/CT has sensitivity ranging from 62% to 100% and improves overall diagnostic accuracy by 5% to 22% compared to CT alone (270–272). Fused PET/CT makes a greater incremental contribution to per-lesion accuracy in extra-pelvic sites, particularly because of its ability to characterize metastatic lymph nodes and to correctly differentiate diffuse serosal infiltration along small bowel loops from normal physiological intestinal activity, which often causes false-negative results in standalone PET (270,272). Nevertheless, diagnostic performance in detecting peritoneal carcinomatosis drops dramatically at an implant size threshold of 4–6 mm because of the limited spatial resolution of the gamma camera and the minimum level of FDG uptake that must be present for detection to occur (273,274). Another potential source of false-negative findings is mucinous tumors, which are associated with less FDG uptake.

Detecting Persistent or Recurrent Ovarian Cancer

The combination of clinical assessment and CA-125 measurement is routinely used to monitor patients treated for ovarian cancer in many institutions (275). However, CA-125 is limited as a tumor marker, since normal values do not exclude the presence of disease, and elevated values do not differentiate between localized and diffuse tumor recurrence (276–278). Furthermore, in the 10% subgroup of biochemically “silent” patients, imaging studies are the only means of assessing treatment response and presence of disease recurrence. Therefore, CT is widely used to

evaluate treatment response and to assess suspected relapse with rising CA-125 levels or clinically suspicious symptoms. Rising CA-125 levels may, however, precede clinical recurrence with a median lead time of 3 to 5 months (275). CT is reproducible, widely available, and well understood. Ultrasound is often used as the initial examination to investigate new symptoms. MRI is reserved as a problem-solving technique to clarify the nature of indeterminate masses on CT. MRI is also particularly useful if there is suspicion of pelvic sidewall invasion or if surgical resection of a pelvic recurrence is planned (279). Emerging data suggest that PET/CT may help in the assessment of patients with elevated CA-125 levels but negative imaging findings.

Ultrasound

US plays a limited role in the detection of recurrent ovarian cancer. US has the greatest sensitivity in detecting recurrent tumor in the pelvis or around the liver and right hemidiaphragm in the setting of ascites (280). However, US has poor sensitivity for detection of miliary peritoneal seeding and peritoneal implants <2 cm (280,281). Additionally, small, plaque-like lesions on the pelvic peritoneum are often missed on US (281). Despite these limitations, US can reliably confirm a clinical suspicion of gross macroscopic recurrent disease and is more accurate than clinical examination (280,281). US can also be used to guide biopsy of areas of suspected recurrence (1).

Computed Tomography

CT is the most commonly used cross-sectional imaging modality for the detection of persistent and recurrent ovarian cancer (Fig. 11.26). It has been demonstrated that there is a survival benefit when patients with advanced ovarian cancer undergo “optimal” versus “suboptimal” primary surgical cytoreduction or IDS (231,240,282). Patients who have no residual or minimal residual disease (<1 cm), at the end of primary surgery for advanced ovarian cancer, survive longer (231,282,283). Intraoperative surgical assessment through direct visualization and palpation is the current reference standard for evaluation of residual disease in patients with ovarian cancer who undergo primary or interval debulking surgery. This is inherently subjective and can be influenced by a number of factors such as surgeon experience, adequate exposure and evaluation of tumor sites, and surgeon and patient expectations (284,285).

FIGURE 11.26. Recurrent ovarian carcinoma. Contrast-enhanced CT images in a patient with a previous history of ovarian cancer. A large solid mass is seen in the right adnexa (T in A). Multiple peritoneal deposits are seen in the undersurface of the right hemidiaphragm as well as a large subserosal liver deposit with deep invasion into the liver parenchyma (arrows in B).

CT has been used to more objectively assess residual disease following surgery. Two studies have compared the surgeons' operative assessments of residual disease to those identified on postoperative CT in patients with advanced ovarian carcinoma reported to have undergone optimal primary cytoreductive surgery. They found that there was only a 52% to 58% correlation between surgeons' assessments and postoperative CT evaluations of residual disease in patients for whom surgeons had reported optimal cytoreduction (286,287). Whereas the reliability of the direct visualization and palpation at completion of surgery is unquestionable, the estimation of the size or the volume of residual disease is far from accurate. Therefore, the additional value of postoperative CT may lie in those cases where there is surgical small-volume residual disease (visible but reported as <1 cm) (287).

Second-look surgery is no longer routinely performed; therefore, imaging diagnosis of recurrence is important, as secondary cytoreduction is only considered if complete resection is possible with no residual tumor. CT is widely used to assess suspected relapse with rising CA-125 levels or clinically suspicious symptoms. The sensitivity of CT ranges from 51% to 84% and its specificity ranges from 81% to 93% (288–290). False-positive results are usually caused by misdiagnosis of adherent bowel loops as a tumor mass. The sensitivity of CT for disease detection is proportional to lesion size. Many studies report limitations in the detection of small tumor nodules in the mesentery and along peritoneal surfaces (288,290). However, the use of sagittal and coronal reformatted images improves the detection of peritoneal implants (248).

If recurrent ovarian cancer is detected by CT, determination of resectability is an important next step. Currently, there is no consensus on CT criteria for determining nonresectability. However, Funt et al. (288) determined that hydronephrosis and invasion of the pelvic sidewall were most indicative of tumor nonresectability. CT-guided biopsy can be used to confirm suspected recurrence (1).

Magnetic Resonance Imaging

MRI plays an important role in evaluation of resectability of recurrent tumor in the pelvis. Recurrent tumor invading the pelvic sidewall represents nonresectable disease (Fig. 11.27). Pelvic muscle or bone invasion confirms sidewall involvement but this should also be suspected when tumor lies within 3 mm of the pelvic sidewall or when the iliac vessels are surrounded or distorted by tumor (Fig. 11.27). A few studies that compared MRI to second-look laparotomy found that dynamic multiphase contrast-enhanced MRI is comparable (sensitivity 90% and specificity 88%) to laparotomy (sensitivity 88% and specificity 100%) and superior to serum CA-125 (sensitivity 65% and specificity 88%) for detecting recurrent peritoneal and serosal deposits (259,291).

Positron Emission Tomography

FDG-PET/CT has been shown to be an extremely useful adjunct in the evaluation of recurrent ovarian cancer (Fig. 11.28). It has sensitivity, specificity, and accuracy of 72% to 100%, 40% to 90%, and 77% to 91%, respectively, for localization of clinical and biochemical recurrence (292–296); in comparison, the

FIGURE 11.27. Recurrent ovarian carcinoma. Axial T2W FSE (A) and DW (B) MR images in a patient with a remote history of ovarian cancer demonstrate a soft tissue mass in the left pelvis (T in A, B). Note that there is no fat plane between the mass and the pelvic sidewall, indicative of pelvic sidewall invasion (arrow in A). The solid component of the mass shows high signal intensity on DWI (T in B). US guided transvaginal biopsy (arrow in C) confirmed recurrent ovarian cancer.

FIGURE 11.28. Recurrent ovarian carcinoma. Unenhanced CT image (A), FDG-PET image (B), and fused PET/CT image (C) demonstrate increased tracer uptake along the serosa of the sigmoid colon. Coronal MIP PET image (D) demonstrates widespread increased tracer uptake along the peritoneal and serosal surfaces in the abdomen and pelvis and avid tracer uptake in a left axillary lymph node (arrow in C).

performance of contrast-enhanced CT in assessing recurrence is inferior (accuracy 43% to 89%), primarily because of low tumor burden at relapse and distortion of pelvic anatomy after cytoreductive surgery (297,298). In two meta-analyses, PET/CT had the highest pooled sensitivity and specificity (91% and 86%, respectively) compared to PET and CT alone, MRI, and CA-125 (299,300). In prospective studies, PET/CT upstaged disease compared to purely anatomical imaging in 55% to 64% of patients by depicting additional sites and altered decisions on clinical management in 34% to 59% of cases, with 44% to 57% of changes rated as high impact (301–304). Fagotti et al. (294) assessed the role of a multimodal approach in the preoperative work-up of patients with recurrent ovarian cancer by prospectively comparing laparoscopy and PET/CT. They reported that combined PET/CT and laparoscopic evaluation had a NPV of 88.9%, a specificity of 59.3%, a PPV of 78.8%, a sensitivity of 95.3%, and an accuracy rate of 81.4%. The number of recurrent nodules identified by PET/CT corresponded to the number found at laparotomy in only 23 patients (40.3%), whereas 15 of 30 patients were correctly diagnosed (50.0%) by staging laparoscopy, suggesting that these techniques are complementary due to the potential of each one to identify a different site of disease recurrence. A recent study found that in patients with recurrent ovarian cancer, size, number, and SUV(max) of peritoneal deposits were significantly associated with poor survival, as were the long- and short-axis diameters, number, and SUV(max)

of distant lymph nodes (290). These preliminary data suggest that tumor size, number, and SUV(max) may have potential as prognostic biomarkers for patients with recurrent ovarian cancer.

In response assessment, a metabolic response defined as a minimum decrease in SUV of 20% after the first cycle and 55% after the third cycle of neoadjuvant chemotherapy was shown to predict macroscopically tumor-free surgery and median overall survival more accurately than clinical, biochemical and histopathological criteria (305). In another study, a cut-off value of 65% SUV reduction had 90% sensitivity, 82% specificity, and 86% accuracy in predicting histological response (306).

VAGINAL CANCER

Vaginal cancer is most often diagnosed and staged clinically. Diagnostic imaging is often performed only for the detection of pelvic lymphadenopathy or metastatic disease, with imaging playing no role in the detection and characterization of vaginal cancer. On MRI, vaginal tumors appear isointense on T1W sequences and may only be apparent if they alter the vaginal contour. On T2W sequences, a vaginal tumor appears as an intermediate to high signal intensity soft-tissue mass (Fig. 11.29) (307–309).

FIGURE 11.29. Vaginal carcinoma. Sagittal (A) and axial T2W FSE MR images demonstrate soft tissue thickening of the posterior vaginal wall (arrow in A, B).

Staging of vaginal cancer is most often clinical (63); however, MRI has a limited role in the staging of vaginal cancer. MRI criteria that correlate to the FIGO staging system have been developed. Stage I disease is defined as tumor that has invaded the epithelium but is confined to the vaginal mucosa. These lesions may be occult on MRI, or there may be abnormal high T2W signal penetrating the vaginal wall. The surrounding perivaginal fat is preserved.

Vaginal tumor that has invaded the paravaginal tissues but does not involve the pelvic sidewall is considered stage II disease. With stage II disease, the normally high-T2W-signal perivaginal fat is invaded by intermediate signal tumor.

Tumor that extends to involve the pelvic sidewall and/or pelvic adenopathy defines stage III disease. Tumor contiguous with the levator ani, obturator internus, or the piriformis muscle is diagnostic of pelvic sidewall invasion. Pelvic adenopathy is diagnosed in the usual manner on MRI.

Stage IV is defined as tumor invading the bladder and/or rectum and/or extrapelvic spread of disease. MRI is particularly well suited for imaging stage IV disease because of its multiplanar capabilities. Invasion of the bladder and/or rectum is diagnosed by identifying disruption of the normal high-T2W-signal mucosa of the bladder and/or rectum. Extrapelvic metastases are diagnosed in the usual manner.

Although these staging criteria have been developed, care must be taken when using MRI for the evaluation of vaginal cancer. It has been shown that inflammatory changes and/or congestion of the vagina may appear similar to carcinoma (307–309). CT and US have little role in the staging of vaginal cancer, although CT can be used for the detection of pelvic lymphadenopathy. Very little data is available on the utility of FDG-PET in vaginal cancer. Lamoreaux et al. demonstrated that FDG-PET was superior to CT in the detection of the primary tumor and pelvic adenopathy in patients with vaginal cancer (310).

Complications from vaginal cancer and/or vaginal cancer treatment can be imaged with US, CT, and/or MRI depending on the clinical concern. Known complications include fistulae, fluid collections, and postradiation therapy colitis. Fistulae are best diagnosed with contrast-enhanced CT or MRI.

VULVAR CANCER

Vulvar cancer is diagnosed and staged clinically. Local tumor extension and lymph node status play an important role in

treatment selection, treatment planning, and prognosis of patients with vulvar cancer, and relapse in the lymph node basin is associated with extremely poor survival. There is no role for diagnostic imaging in the primary detection and characterization of vulvar cancer. However, imaging (MRI) may play a role in evaluation of the local extent of disease in advanced cases, especially if urethral invasion is suspected, as well as in the evaluation of lymphadenopathy (US, CT, MRI) and distant metastatic disease (CT and PET/CT).

Vulvar cancer appears on US as a soft-tissue mass with internal vascularity. On CT, vulvar cancer appears as a nonspecific soft-tissue mass. On MRI, it demonstrates intermediate signal intensity on T1W sequences and high signal intensity on T2W sequences (Fig. 11.30). MRI may be used to evaluate tumor extension into adjacent structures (i.e., urethra) (311,312). MRI may also be used to differentiate recurrence from posttherapy changes, with the former demonstrating high signal intensity on T2W images, and the latter demonstrating intermediate signal intensity on T2W sequences.

The surgical management of early-stage vulvar cancer is now more conservative, and an individualized approach is increasingly used to improve the outcome and reduce the complication rate related to lymphadenectomy (313). Lymphadenopathy in vulvar cancer is usually treated by surgical lymph node dissection. However, sentinel lymph node excision is now being recommended in selected patients with early-stage squamous cell carcinoma (tumor <4 cm in diameter and clinically nonsuspicious groin nodes) as a means to avoid the operative morbidity associated with inguinofemoral lymphadenectomy (314–316). Patients with tumor larger than 4 cm in diameter and with suspected groin nodes will undergo radical excision and lymphadenectomy.

The combination of lymphoscintigraphy with technetium-99 m-labeled nanocolloid and blue dye is the most accurate technique for sentinel node detection (315). Patients with a positive sentinel node should undergo a full inguinofemoral lymphadenectomy followed by a postoperative radiation therapy to the involved groin and pelvis. However, if sentinel lymph nodes are negative, no further treatment is indicated. All vulvar cancers located within 1 cm of midline structures (clitoris, vagina, or anus) have the potential to spread to both groins, and should be treated by radical wide local excision and bilateral inguinofemoral lymphadenectomy.

US combined with fine-needle aspiration biopsy (FNA) of suspicious-looking nodes has been shown to influence surgical management with sensitivity, specificity, NPV, and PPV of 80%,

FIGURE 11.30. Vulvar carcinoma. Sagittal T2W FSE image (A), axial T2W FSE images (B, C), and DW MR image (D) demonstrate a large vulvar mass (T in A, B, D) invading the anus (arrow in B). The mass is of high signal intensity on DWI in keeping with restricted diffusion. Note presence of enlarged left inguinal lymph node (arrow in C) which proved to be metastatic at histopathology.

100%, 93%, and 100%, respectively (317–319). More recently, in a multi-center setting, high-resolution MRI sequences have been shown to achieve an accuracy of 87% in detection and characterization of inguinal (Fig. 11.30) and pelvic lymph nodes (312), indicating that MRI may be useful to triage patient for US-guided biopsy versus sentinel lymph node detection.

Very little has been published on the use of FDG-PET for vulvar cancer. In one study, FDG-PET had sensitivity of 80%, specificity of 90%, PPV of 80%, and NPV of 90% in the detection of pelvic adenopathy (320). Although these results are promising, more research in this area is needed.

CONCLUSION

Increased use of CT, MRI and PET/CT for staging gynecologic pelvic malignancies has led to a significant decline in the use of conventional and invasive radiologic studies such as intravenous urography and barium enema, which are now considered obsolete at most institutions. In addition, although US is the primary imaging modality for characterizing ovarian masses and evaluating the endometrium, US is no longer used for primary gynecologic cancer staging.

CT has a central role in pelvic imaging, mainly because of its relatively low cost, high spatial resolution, fast examination

times, and wide availability. CT is the modality of choice for staging ovarian cancer, detecting distant metastases and lymphadenopathy in endometrial and cervical cancer, and evaluating recurrent pelvic malignancies. Both US and CT are used to guide percutaneous drainage and biopsy.

MRI plays important roles in the management of gynecologic malignancies, ranging from initial evaluation of disease extent, to aiding treatment selection, to follow-up. In patients with endometrial cancer, MRI improves pretreatment risk stratification. It enables accurate surgical planning and selection of patients for pelvic or paraaortic lymph node dissection in high-risk disease, whilst obviating the need for extended surgery in patients with low-risk disease. In patients with cervical cancer, MRI improves FIGO clinical staging accuracy, leading to better treatment selection and planning. In those patients who wish to preserve fertility, MRI plays a paramount role in assessing eligibility for fertility-sparing surgical procedures. In patients with ovarian cancer, MRI is a problem-solving modality. There is growing evidence that DW-MRI may enable more accurate mapping of the extent of peritoneal disease than does CT. MRI certainly plays an important role in patients with recurrent ovarian cancer by assessing resectability in cases of solitary pelvic recurrences.

FDG-PET/CT is increasingly being used to evaluate gynecologic malignancies. It is useful in the primary staging of cervical cancer as well as the detection of recurrent ovarian, cervical, and endometrial cancers.

Biologic and Physical Principles of Radiation Oncology

BETH A. ERICKSON ■ JASON ROWND ■ KEVIN KHATER

RADIATION ONCOLOGY AS A SPECIALTY

Radiation oncology is a specialty focused primarily on the treatment of malignancies, although there are a number of benign diseases for which radiation can be used. Training in radiation oncology begins with internship, followed by 4 years of residency. Board certification follows, requiring successful completion of both written and oral exams. Residency training includes an in-depth understanding of the natural history and treatment of all malignancies including the roles of surgery and systemic therapy in this era of multimodality therapies. An in-depth understanding of surgical procedures, pathology, and radiologic anatomy, as well as the efficacies and toxicities of systemic therapy, is required. Formal instruction in physics and radiobiology is also part of the residency training. Subspecialization can follow with a specific practice focus on gynecologic or other cancers. Only a few centers sponsor fellowships, which are usually focused on brachytherapy or other special procedures. Brachytherapy skills are especially important in the curative treatment of patients with gynecologic cancer. In addition, contemporary treatment of gynecologic malignancies requires mastery of rapidly evolving technology for delivering external beam irradiation with techniques such as intensity-modulated radiation therapy (IMRT) and image-guided radiation therapy (IGRT). Radiation oncologists are important contributors in the management of individual patients and in multidisciplinary tumor boards. Having a knowledgeable and subspecialized radiation oncologist and gynecologic oncologist paired is a great benefit to all. In addition to radiation oncologists, other allied health professionals are integral to the radiation oncology department and treatment delivery. Radiation therapists are the individuals who actually operate the radiation equipment and deliver the radiation treatments. Some of them will obtain a Bachelor of Science degree followed by a 13-month training program in radiation therapy. Alternatively, a 2-year associate degree in diagnostic radiology can be obtained followed by 1 to 2 years in radiation therapy training. Dosimetrists are primarily responsible for planning the radiation therapy or dosimetry prior to treatment delivery. Most of these individuals are former radiation therapists. An additional 1 to 2 years of training under a physicist and board-certified dosimetrist and additional years of practice are required to be eligible for board certification. Radiation physicists supervise and review the work of dosimetrists. Physicists are also integral to the introduction and maintenance of the rapidly evolving technology in radiation oncology departments. They are very involved with quality assurance and radiation safety. They can be Master's-level or PhD-level physicists and should be board certified.

INTRODUCTION TO RADIOBIOLOGY

Radiobiology is the study of the action of ionizing radiations on living things (1). It is important for radiation oncologists to know the most appropriate dose to potentially eradicate the tumor and the normal tissue tolerance doses for those organs in the radiation field. The published literature includes clinical and laboratory data to support various dose/fractionation schemes as well as acceptable dose ranges to the normal tissues. The size and histology of the tumor as well as the relationship of the tumor to the normal organs within the radiation field will help to determine the total dose and the dose per fraction. Almost every radiation oncologist approaches treatment planning by considering whether the therapy is curative versus palliative. If curative, then the focus becomes identifying the location of the disease and how best to eradicate it. Typically, radiation and chemotherapy treatments take place over many months, and upon completion of treatment, if there is still a clonogenically viable cell that remains, then the tumor will ultimately recur. Clinical radiobiology focuses on steps that maximize the chance for cure and decrease the chance for side effects.

As in pharmacology, radiation effects exhibit a sigmoidal dose-response curve. In the case of radiation, the interpretation of the curve becomes far more complex because multiple independent processes govern responses to radiation. Pharmacology, on the other hand, tends to be simpler because classic examples can be described by a ligand binding to a group of receptors initiating subsequent events. Keeping this in mind, consider the following theoretical dose-response curve for tumor control probability and normal tissue complications in the presence and absence of chemotherapy (Fig. 12.1). Ideally, there is a great deal of separation between the curve on the left, representing chances of tumor control, and the curve on the right, representing the chance for toxicity. An intolerable situation is where the curves are close together since, as they approach one another, the chances of control and toxicity become equal and the therapeutic range (TR) narrows. Therefore, the most important goal of radiobiology is to understand the basic science behind the interaction of radiation and cells with the hope of maximizing the risk-benefit ratio for patients.

Models for Cell Kill

Tumor Control Probability

The simplest model one can envision for the sterilization of cancer cells by radiation in a given volume is the log cell kill model. A typical course of radiation therapy is given in 10 to 40 fractions

FIGURE 12.1. Theoretic curves for tumor control and complications as a function of radiation dose both with and without chemotherapy. TR, therapeutic range, or the difference between tumor control and complication frequency.

Source: Reprinted from Perez CA, Thomas PRM. Radiation therapy: basic concepts and clinical implications. In: Sutow VVV, Fernbach DJ, Vietti TJ, eds. *Clinical Pediatric Oncology*. 3rd ed. St. Louis: Mosby; 1984:167, with permission from Elsevier.

administered over 2 to 8 weeks. Each fraction kills a fixed percentage of cells. We are trained at a young age to mathematically think in base 10, and therefore a convenient number to consider is the D_{10} or the dose that kills 90% of the cells. If there are 100 cells and a D_{10} dose is administered, 10 viable cells remain. D_{01} , a commonly used term, is the dose of radiation that kills 63% of cells. D_{01} is related to the more convenient parameter D_{10} by the following formula: $D_{10} = 2.3 \times D_{01}$. Consider a tumor 1 g in size, which has 10^9 cells. If the D_{10} for this tumor is 3 Gy, how many fractions are required for a 90% chance of sterilization? The log cell kill model gets slightly more complicated when dealing in fractions, as 1/10 of a viable cell does not exist. Instead, 0.1 cells represent a 10% chance that a viable cell will exist at the end of therapy. Therefore, a tumor with 10^9 cells requires 10 decades of cell kill for a 90% chance of tumor control. Three Gy $\times$ 10 fractions = 30 Gy total dose. This model makes a number of invalid assumptions such as D_{10} remaining constant throughout the course of radiation. As discussed later, there are data that support D_{10} both increasing and decreasing throughout treatment.

When it comes to actually treating patients, physicians do not actively engage in the above mental exercise. However, the basic concepts of the log kill model are reflected in the administered treatments. Consider, for example, curative therapy for cervical cancer. Radiation oncologists begin treatment planning by first identifying the targets GTV (gross target volume) and CTV (clinical target volume) (Fig. 12.2). The CTV is any region that has a high likelihood of harboring malignancy, but otherwise appears normal. For cervical cancer, this could be normal-sized pelvic and possibly paraaortic lymph nodes or an area of positive margin. The CTV typically requires a lower dose of radiation for control, ranging from 45 to 54 Gy. The GTV is defined as any disease that is identified either radiographically or by physical exam, and requires a higher dose of radiation, such as 80 to 90 Gy, in cervical cancer patients. Attaining these doses of radiation while respecting normal tissue tolerance is not feasible with external beam radiation therapy alone and brachytherapy is required. If a patient undergoes a hysterectomy where bulk tumor is removed, then there is not a GTV and brachytherapy is often not needed. So, while the cell kill model is of little practical importance, it is used nonquantitatively for almost every patient receiving radiation treatments.

FIGURE 12.2. Target definition in radiation treatment planning for cervical cancer. The solid circle represents the gross target volume (GTV), which is the cervical primary defined both clinically and radiographically. The clinical target volume (CTV) is the pelvic lymph nodes, which have a high probability of at least microscopic involvement. The planning target volume (PTV) is shown as the outer solid line and represents the margin added to the CTV to account for organ motion and daily setup error.

Cell Survival Curves

The log cell kill model describes cell kill in very simplistic terms such that a given radiation dose will kill a certain percentage of cells and that a tumor receiving a fractionated course of radiation gets progressively smaller with time. This approach looks at behavior in a population of cells, which is practical, but gains very little insight into events at the molecular level. The reason is that measuring the diameter of the tumor is not a very accurate way of estimating cell kill. Additionally, tumor cells may have undergone clonogenic cell death, wherein they are still present but unable to reproduce. Therefore, one does not necessarily have to kill all cancer cells in order to achieve cure if the remaining ones are unable to reproduce.

In order to understand events at the molecular level, one needs to accurately measure cell kill. The technique used most commonly first involves creating a suspension containing the target population of cells at a known concentration (Fig. 12.3). An aliquot with a known number of cells is plated on agarose growth media and allowed to incubate. As one would expect, not all the cells successfully form a colony, and so plating efficiency must be calculated by dividing the number of formed colonies by the starting number of cells. The experiment is repeated, but after plating and before incubation, the petri dish is irradiated. The number of colonies formed is divided by the starting number of cells, which is then divided by plating efficiency to yield the ratio of surviving cells. This experiment is repeated over a range of doses of radiation and under various conditions to yield a cell survival curve. The first feature to notice about a cell survival curve is that it uses a logarithmic scale on the y-axis such that as survival approaches 0, the curve goes to negative infinity. The benefit of plotting the data on a logarithmic scale is that, visually speaking, we are able to interpret whether the events driving cell kill are simple or complex. Consider the analogy of a completely different process, such as the decay of a pure radioisotope over time. Plotting this on a linear scale over time would yield an exponential curve, which is difficult to interpret.

FIGURE 12.3. Cell culture technique used to generate a cell survival curve. A cell suspension is used to plate Petri dishes with a known number of cells, which are subsequently irradiated. Viable cells will form colonies after incubation. The number of viable cells divided by the plating efficiency is used to calculate the surviving fraction. The experiment is repeated over a wide range of doses to produce the cell survival curve.

However, plotting this on a logarithmic scale would yield a perfect straight line, indicating that a single isotope is involved. Consider a slightly more complex situation where the decay is represented by 2 radioactive isotopes with similar half-lives. Plotting this on a linear scale would also reveal an exponential curve, which is unrevealing by inspection. However, creating a plot on a logarithmic scale would yield 2 lines superimposed on one another, clearly indicating that 2 radioisotopes are involved.

Two theoretical experimental cell survival curves are shown in Figure 12.4 under LDR (low-dose-rate) and HDR (high-dose-rate) radiation conditions. The curve for LDR is best fit by a straight line, while the HDR curve is shown to have 2 components, an earlier linear component mirroring the LDR curve followed by a quadratic component. At higher doses of radiation, the HDR curve always has a higher proportion of cell kill than the LDR curve for any given dose.

The rate at which radiation is delivered causes dramatic differences in the shape of the cell survival curve. This is best described by considering the linear-quadratic model with DNA as the lethal target. The evidence for DNA as one of the targets for radiation is substantial: (a) incorporation of radioactive tritium into DNA causes cell death at greater rates than cytoplasmic tritium (2); (b) halogenated pyrimidines, when present in DNA, increase the cell's inherent radiosensitivity in an amount proportionate to the degree of incorporation; (c) a correlation between radiation, DNA double-stranded break repair, and clonogenic survival has also been observed; (d) the concentration of DNA in the nucleus correlates positively with radiosensitivity (3); (e) microirradiation techniques have shown the nucleus to be the most radiosensitive organelle (4).

In most instances, radiation must cause DNA damage that results in a net loss of genetic material, thereby causing a lethal outcome. Radiation exerts most of its deleterious effects by causing breaks in the DNA backbone. Figure 12.5 shows possible

outcomes of photon interaction with the DNA backbone. Because DNA is composed of a double helix with multiple local base pairs acting cooperatively, a single-strand nick is thought to be inconsequential and is repaired by the cellular machinery (Fig. 12.5B). In fact, multiple single-strand nicks can occur, and if they are remote from one another, a normal cell can repair the damage with little chance of a deleterious outcome (Fig. 12.5C). However, 2 opposing single-strand breaks locally disrupt cooperativity, and a double-stranded break (DSB) develops.

FIGURE 12.4. Cell killing by radiation is largely due to aberrations caused by breaks in 2 chromosomes. The dose-response curve for high-dose-rate irradiation is linear-quadratic: the 2 breaks may be caused by the same electron (dominant at low doses) or by 2 different electrons (dominant at higher doses). For low-dose-rate irradiation, where radiation is delivered over a protracted period, the principal mechanism of cell killing is by the single electron. Consequently, the LDR survival curve is an extension of the low-dose region of the HDR survival curve.

FIGURE 12.5. Diagrams of single- and double-strand DNA breaks caused by radiation. **A:** Two-dimensional representation of the normal DNA double helix. The base pairs carrying the genetic code are complementary (i.e., adenine pairs with thymine, guanine pairs with cytosine). **B:** A break in one strand is of little significance because it is readily repaired, using the opposite strand as a template. **C:** Breaks in both strands, if well separated, are repaired as independent breaks. **D:** If breaks occur in both strands and are directly opposite or separated by only a few base pairs, this may lead to a double-strand break, where the chromatin snaps into 2 pieces.

Once a DSB develops, the cell attempts repair by rejoining the cut ends, as shown in Figure 12.6. There are 2 possible outcomes with repair of the DSBs: the lethal outcomes are shown at the top of Figure 12.6, wherein the chromosomes rearrange such that a portion lacks a centromere, an acentric fragment. When the cell undergoes mitosis, these acentric fragments are eventually lost and may be identified in micronuclei, a smaller “subnucleus” found in the cytoplasm in a separate compartment from the chromosomes (5,6,7). The nonlethal outcomes are shown at the bottom of Figure 12.6, where repair results in a reciprocal translocation and preservation of the genetic information. In some instances, the reciprocal translocation results in activation of an oncogene, which may manifest as a malignancy. It is worth noting that a “bystander effect” has been described using microbeam irradiation techniques (8). In this approach, a nanoscale α -particle beam is directed at the nucleus of a single cell. DSBs can be seen to develop in immediately adjacent unirradiated cells. This is just one notable example where classic radiation DNA damage models fail to explain an observation.

With the above information, the differences in the shape of the cell survival curve under HDR versus LDR conditions can be more easily understood. Referring back to Figure 12.4, in the inset is shown the linear-quadratic model depicting 2 DSBs that develop as result of a photon ejecting an electron, which interacts with DNA. Recall from Figure 12.6 that 2 separate chromosomal breaks are necessary for a potentially lethal outcome. Above the quadratic model is the linear model represented as a single ejected electron causing both DSBs and described mathematically by $\epsilon\alpha D$, where ϵ and α are both constants and D is dose. The important point is that the degree of the linear component of cell kill, also known as α kill, is proportional to D since only one photon/electron is involved. The quadratic model also shows 2 chromosomal breaks. This is caused by 2 separate ejected electrons and is described by $\epsilon\beta D^2$, where ϵ and β are constants and D is dose. Cell kill accounted for by the quadratic model, or β kill, is proportional to D^2 because 2 photons/electrons are involved. Looking at the HDR curve at low doses

FIGURE 12.6. Most biologic effects of radiation are due to the incorrect joining of breaks in 2 chromosomes. For example, the 2 broken chromosomes may recombine to form a dicentric (a chromosome with 2 centromeres) and an acentric fragment (a fragment with no centromere). This is a lethal lesion resulting in cell death. Alternatively, the 2 broken chromosomes may exchange broken ends, called symmetrical translocation, which does not lead to death of the cell, but in a few special cases activates an oncogene by moving it from a quiescent to an active site.

FIGURE 12.7. Influence of oxygen tension on radiosensitivity. Survival curve for human embryo liver cells in tissue culture irradiated with and without oxygen.

of radiation, there is very little β kill; however, at higher doses, the β component increases exponentially because of D^2 . Under LDR conditions, the β component is absent, leaving only α kill. This is best explained by the idea that β kill involves damage to one chromosome and so is more easily repaired provided that the radiation dose rate and rate of DSB formation is not significantly greater than the cell's repair capacity.

DNA Damage Repair and the Shape of Cell Survival Curves

The concept that DNA damage repair drives the shapes of cell survival curves is well illustrated by experiments showing the effectiveness of oxygen as a sensitizer. Oxygen is known to chemically modify radiation-induced DNA damage making it irreparable (8). This is known as the oxygen fixation hypothesis. Therefore, under anoxic conditions, DNA damage repair would be expected to increase considerably. Figure 12.7 shows an experiment on cultured human embryo liver cells irradiated under 100% oxygen and nitrogen conditions. Hypoxia causes the cell survival curve to shift to the right and change shape.

Up to this point, the linear-quadratic model has been used to describe cell survival curve experiments. Another way to describe the observations is using the multitarget single hit model, which simply states that multiple targets within a cell must be damaged for a lethal outcome. Therefore, at very low doses of radiation, there will be nearly 100% survival. The model is described mathematically by $\text{Survival} = 1 - (1 - e^{-D/D_0})^n$, where D is dose delivered, D_0 is the amount of radiation to achieve approximately 63% cell kill. The parameter n is the extrapolation coefficient or the number of targets in each cell, and is identified by where an imaginary straight line drawn back from the linear portion of the cell survival curve crosses the y -intercept. It is important

to note that this model makes no statement about what the targets actually are. Since we already know that the primary target is DNA, which can trigger multiple complicated events such as repair and apoptosis, the multitarget single hit model falls short of perfection. Nevertheless, it is a good model for understanding the general shapes of survival curves. Contrast this model to the single-target single hit model, which states that a cell needs only to sustain a single hit for lethality, and is described mathematically by $\text{Survival} = e^{-D/D_0}$. Therefore, even at very low doses of radiation, there will be cell kill. Note that this model does not have an extrapolation coefficient.

Referring back to Figure 12.7, the cell survival curve under anoxic conditions can be interpreted as having a higher extrapolation coefficient when compared to 100% oxygen. The extrapolation coefficient is shown diagrammatically by following the dotted lines of the survival curves back to the y -intercept. The dotted line crosses the y -intercept at n .

The inset shows a dose-response relationship between oxygen and radiosensitivity. The typical sigmoidal relationship is lost because oxygen is extremely effective at fixing DNA damage even at low pressures. In fact, only approximately 20 mm Hg or 2% to 3% oxygen is required to achieve the maximum oxygen effect. The half-maximum sensitization is typically observed at 3 mm Hg or 0.5% of oxygen.

The linear-quadratic model is stated more explicitly by the following equation:

$$-\ln S = \alpha D + \beta D^2$$

where S is the surviving fraction and the remaining parameters α , β , and D are the same definitions as above. The formula was used to generate Figure 12.8. The dashed line represents the α component and is generated by extrapolating the initial slope of the curve to higher doses of radiation. The point at which the α and β kill are equal is shown, and the dose at which this occurs is called

FIGURE 12.8. At a dose equal to the α/β ratio, the log cell kill due to the α process (nonreparable) is equal to that due to the β process (reparable injury): α/β is thus a measure of how soon the survival curve begins to bend over significantly.

the α/β ratio. It is worth noting that the α/β ratio is a bit of a misnomer, as ratios typically are unitless values. However, α/β has the units of Gy^{-1} . The α/β ratio for early side effects is thought to be higher, around 10 Gy^{-1} , than for tumor control and late side effects, which is around 3 Gy^{-1} .

Biologically Equivalent Dose

It is clear from Figure 12.4 that both the total dose of radiation and how fast it is delivered can produce very different outcomes. The same holds true for fractionated courses of radiation. For example, 16 Gy delivered in a single treatment, as is the case for radiosurgery, can sterilize a small tumor of cancer cells. However, the same treatment delivered over 8 days would be clinically insignificant. Figure 12.9 shows theoretical cell survival curves for early and late reactions under two separate experimental conditions, single fraction and multifraction regimens. Note that by breaking up the radiotherapy in fractions, the shoulder of the

FIGURE 12.9. Difference in cell survival curves for acute and late radiation effects with single or multifractionated doses of irradiation.

Source: Reprinted from Fowler JF. Fractionation and therapeutic gain. In: Steel GG, Adams GE, Peckham MT, eds. *Biologic Basis of Radiotherapy*. Amsterdam: Elsevier Science; 1983:181, with permission from Elsevier.

cell survival curve is repeated. A formula that would normalize a biologic endpoint under various dose fractionation schemes is necessary. The linear-quadratic equation can be used to derive an equation to be used as a guide to predict various biologic endpoints and is given by the following equation:

$$\text{BED} = D[1 + d/(\alpha/\beta)]$$

Where:

BED = biologically equivalent dose

D = total dose

d = dose per fraction

α/β = dose where the α component of cell kill equals the β component

A good example where the formula aided the design of a randomized trial, RTOG 8305, is shown below (9). This trial investigated two different fractionation schemes in the treatment of metastatic melanoma.

Early Side Effects (assumes an α/β of 10)

Arm 1 (32 Gy at 8 Gy/fxn):

$$\begin{aligned}\text{BED} &= D[1 + d/(\alpha/\beta)] \\ &= 32 \text{ Gy} (1 + 8 \text{ Gy}/10 \text{ Gy}) \\ &= 57.6 \text{ Gy}\end{aligned}$$

Arm 2 (50 Gy at 2.5 Gy/fxn):

$$\begin{aligned}\text{BED} &= D[1 + d/(\alpha/\beta)] \\ &= 50 \text{ Gy} (1 + 2.5 \text{ Gy}/10 \text{ Gy}) \\ &= 62.5 \text{ Gy}\end{aligned}$$

Late Side Effects/Tumor Control (assumes an α/β of 3)

Arm 1 (32 Gy at 8 Gy/fxn):

$$\begin{aligned}\text{BED} &= D[1 + d/(\alpha/\beta)] \\ &= 32 \text{ Gy} (1 + 8 \text{ Gy}/3 \text{ Gy}) \\ &= 117 \text{ Gy}\end{aligned}$$

Arm 2 (50 Gy at 2.5 Gy/fxn):

$$\begin{aligned}\text{BED} &= D[1 + d/(\alpha/\beta)] \\ &= 50 \text{ Gy} (1 + 2.5 \text{ Gy}/3 \text{ Gy}) \\ &= 92 \text{ Gy}\end{aligned}$$

In this instance, the BED calculations predict that arm 1 will have slightly more early and late side effects but better tumor control. BED calculations are used as a guide for determining doses. Oftentimes the calculations do not translate directly into the clinical setting outcomes. For example, RTOG 8305 was not able to detect a difference between the two dose fractionation schemes.

The Cell Cycle

The cell cycle is an ordered set of events, resulting in cell growth and division into two daughter cells. The steps pictured in the middle of Figure 12.10 are G_1 -S- G_2 -M. The G_1 stands for “gap 1,” and S phase stands for “synthesis” and is the point at which DNA replication occurs. Late S phase is the most radioresistant phase of the cell cycle since the DNA repair machinery for replication can also repair radiation damage. The G_2 stage stands for “gap 2,” and M phase stands for “mitosis” and is when nuclear division occurs. M phase is also the most radiosensitive phase of the cell cycle since this is an all or nothing event. In other words, once the cell enters into M phase, it will attempt to complete this phase of the cycle without arresting. Therefore, any DNA damage caused generally will be passed along to the daughter cells and may be fatal. This is one important reason why rapidly dividing cells such as cancers are radiosensitive. Not shown in

FIGURE 12.10. The cell cycle and important molecular biologic pathways driving cell cycle arrest, apoptosis, and survival are shown. The solid pentagon denotes a net inhibitory step and the open circle indicates a downstream step.

Figure 12.10 is G_0 , which is a stable state of the cell and is typically observed with well-differentiated cells that have reached end stage of development and are no longer dividing (i.e., neuron).

There are three major classes of proteins that orchestrate the cell cycle in mammalian cells: (a) cyclins, (b) cyclin-dependent kinases (cdk in mammals, cdc in yeast), (c) proteins that regulate (a) and (b). Cyclins are generally synthesized and degraded for each phase of the cell cycle. Alone they have no intrinsic enzymatic activity; rather, they bind to and activate cdks. Monomeric cdks are protein kinases that are inactive and require association with a specific cyclin and phosphorylation of a series of conserved threonine residues to become active. Cyclin D/cdk4 is involved with G_1 phase of the cell cycle, cyclin E/cdk2 with G_1 to S phase, cyclin A/cdk2 with S to G_2 , and cyclin B/cdk1 with M.

Cellular Response to Radiation

When a cell is irradiated, there are, in general, four possible outcomes. The cell can survive, undergo apoptosis, undergo a mitotic death, or senesce. Survival requires cell cycle arrest and repair of damaged DNA. Apoptosis requires intact molecular biologic pathways that favor an ordered process of programmed cell death within hours of exposure to radiation. Unfortunately, most tumors have mutations in these pathways, but in malignancies such as lymphoma where these pathways are intact, the tumors can respond after only a couple of radiation treatments. Cells that die a mitotic death undergo a catastrophic event when trying to replicate and so responses may take days. Tumors that die via this mechanism are more radioresistant and result in necrotic masses on imaging after completing a course of radiation. Senescence is a state in which proliferation is irreversibly arrested and the cell may eventually die. Note that senescence is a metabolically active state, which is different from G_0 , which is typically metabolically inactive.

Inherent to the cell is a type of thermostat, which influences the radiation responses to favor any of the above processes. Protooncogenes are regulator proteins that, due to either overexpression or mutation, have a higher activity level, thereby promoting unregulated division. Because this mechanism is a net gain of function, only one allele needs to be affected in order to see phenotypic expression. Tumor suppressor genes keep the cell cycle in check, and so loss of function of both alleles is typically required for dysregulation to be observed.

Cell Cycle Arrest

As previously mentioned, when a cell is irradiated, repair of the DNA backbone is attempted, and in order for this process to occur the cell cycle must typically arrest. There are two prototypical points in the cell cycle during which arrest occurs: G_1 and G_2 (10,11). A major regulator of the cell cycle is the transcription factor p53, which is a tumor-suppressor gene that has many pathways both upstream and downstream and is important for G_1 arrest (Fig. 12.10) (12). For example, breaks in the DNA backbone are rejoined via the nonhomologous end-joining (NHEJ) repair mechanisms (top left of Fig. 12.10) (13). One critical gene, the ataxia telangiectasia gene (ATM) has a net positive regulatory effect on p53, which, via p21 (CCDN1A), has a net inhibitory effect on cyclin D/cdk4, thereby favoring arrest. This is the p53-dependent pathway of cell-cycle arrest. An alternative pathway, independent of p53, operates via chk1/2 and 14-3-3 α gene products and has a net inhibitory effect on cyclin B/cdk1, which promotes arrest during G_2 (14).

Retinoblastoma Gene, E2F, and Human Papillomavirus

Retinoblastoma protein (Rb) is another critical regulator of the G_1 phase of the cell cycle (15). This gene is located on chromosome

13 and mutations can cause a number of tumors, the earliest of which to manifest is retinoblastoma. Knudson et al. developed the two-hit hypothesis for the inheritance pattern of this disease (16). He recognized that there were 2 forms: (a) sporadic, which comprises 60% of the cases of retinoblastoma, whereby mutations occur as random events in both alleles. Patients typically have unilateral disease and a marginal risk for developing second malignancies in response to radiation; and (b) Inherited, where a germ-line mutation results when an abnormal allele is inherited from a parent. Patients with this form of retinoblastoma are more likely to develop bilateral disease and have a profound sensitivity toward developing radiation-induced second malignancies. Rb acts by binding and inhibiting E2F, a transcription factor essential for G_1 . Phosphorylation of Rb results in release of inhibition of E2F and subsequent cell cycle progression. Human papillomavirus gene product produces an oncogene, E7, which binds to Rb and releases inhibition of E2F, thereby promoting cell division (17).

Apoptosis

Apoptosis can begin in 2 distinct manners: (a) extrinsic pathway, where the apoptotic stimulus occurs extracellularly, or (b) intrinsic pathway, where the cascade of events is contained intracellularly. Figure 12.10 shows both pathways converging on caspase 8 (cysteine aspartic acid-specific proteases). Caspases are expressed as inactive precursors (procaspases), which are proteolytically cleaved to an active state following an apoptotic stimulus. Upstream from caspase 8, the pathways diverge. The extrinsic pathway begins by binding of a specific ligand such as Fas-L or tumor necrosis factor (TNF) to a membrane-bound death receptor. The intrinsic pathway, on the other hand, requires disruption of the mitochondrial membrane and release of mitochondrial cytochrome c to the cytoplasm. Cyt c then combines with 2 other cytosolic protein factors, Apaf-1 (apoptotic protease activating factor-1) and procaspase-9, to promote the assembly of a caspase-activating complex termed the apoptosome, thereby promoting the apoptotic caspase cascade. Bcl-2 and its family member proteins are important regulators of apoptosis. Bcl-2 is antiapoptotic by inhibiting proapoptotic factor bax and inhibiting the release of cyt c into the cytoplasm. p53 is an important inhibitor of bcl-2. All of these pathways interact to determine whether a cell will survive or apoptose in response to an insulting stimulus such as radiation.

Radiation Effects on Embryo and Fetus

In Utero Exposure to Ionizing Radiation

There are 2 models that describe the negative clinical sequelae of exposure to radiation to a developing fetus or embryo. (a) Deterministic effects describe how radiation affects a large population of cells resulting in end organ damage. A large number of cells must die in order to induce organ failure. As such, deterministic effects tend to have a sigmoidal dose-response relationship with a threshold dose. As long as the threshold dose is respected, there is very little chance of a given toxicity. (b) Stochastic effects describe events at the cellular level and how radiation induces malignancies. Stochastic effects have more of a constant, steep dose-response relationship. As such, there is no threshold dose; that is, exposure to even miniscule amounts of additional radiation theoretically increases the chance of inducing a malignancy.

Deterministic Effects—End Organ Damage and Failure

The most sensitive phase of the cell cycle to ionizing radiation is M phase because little repair to the DNA backbone occurs

FIGURE 12.11. Summary of the effects of radiation on the developing embryo and fetus from 3 principal sources: medical radiation, laboratory animal studies, and survivors of the atomic bomb attacks on Nagasaki and Hiroshima. The animal studies indicate a wide range of structural abnormalities during organogenesis, whereas the principal effect observed in humans is reduced head diameter with or without severe mental retardation.

Source: Modified from Hall EJ. *Radiobiology for the Radiologist*. 4th ed. Philadelphia: JB Lippincott Co.; 1994, with permission.

during this period. Most of the cell molecular machinery is geared toward completing mitosis and any DNA double-stranded breaks are passed along to the daughter cells and are typically fatal. Since embryos and fetuses are composed of rapidly dividing cells, they are exquisitely sensitive to radiation and exhibit an extremely low threshold dose. Gestational age is also a key determinant when predicting outcomes of radiation exposure. As Figure 12.11 shows, exposure of several gray during the first 1 to 2 weeks of gestation (peri-implantation stage) results in loss of the embryo. However, if the embryo survives the insult, it will go on to develop without obvious abnormalities. This phenomenon is termed the “all or nothing effect.” During weeks 2 to 6, the period of organogenesis is occurring and exposure at this point results in congenital anomalies, neonatal death, and temporary growth retardation. Doses as low as 2 Gy have a 70% mortality. The fetal period occurs beyond 6 weeks and exposure results in permanent growth retardation. Irradiation during weeks 4 through 16 may produce severe eye, skeletal, and genital organ abnormalities as well as microcephaly and mental retardation. According to the Japanese survival data, the risk is approximately 40% per gray. Exposure during weeks 16 through 20 may cause a less severe form of stunting of growth, microcephaly, and mental retardation. After 30 weeks, low doses of radiation do not typically result in gross abnormalities.

Stochastic Effects—Cancer Induction

The Oxford Survey by Kneale and Stewart suggested that there was an association between leukemia risk and *in utero* exposure to diagnostic X-rays (18). Doll and Wakeford summarized the data with the following general conclusions: Low-dose irradiation increases the risk of childhood malignancies, particularly in the third trimester (19). An X-ray exam increases the risk

by approximately 40% above the spontaneous rate. Doses as low as approximately 10 mGy increase the risk, and the excess absolute risk is around 6% per gray. Solid tumors have a longer latency period of approximately 20 to 40 years, whereas leukemias have an average latency of around 7 years. When counseling the pregnant patient or worker, it is important to let them know the magnitude of and potential for side effects. According to the International Council of Radiation Protection (ICRP) Publication 84, doses less than 1 mGy may be considered negligible, which is the approximate dose of normal background radiation (20). Exposures above 1 mGy require a more in-depth discussion with the patient. ICRP Publication 84 provides detailed risk assessments and counseling guidelines for *in utero* exposure.

Occupational Exposure

Once pregnancy has been declared, the employee is encouraged to formally inform her employer. Further, the radiation safety officer should interview her, her employment should be evaluated for exposure history, and steps should be taken to minimize exposure. The National Council on Radiological Protection recommends that the embryo/fetus have limited exposure to less than 0.5 Sv/month (21).

INTRODUCTION TO RADIATION PHYSICS

Radiation physics is the study of the interaction of radiation with matter. In the treatment of patients with radiation, this matter is either tumor tissue or normal tissues such as the skin, the internal organs, or the supporting tissues and structures.

Units Used in Radiation and Radiation Therapy

Radiation is an abbreviation for electromagnetic radiation. It can occur in numerous forms. The most common forms used in radiation therapy are X-rays, γ -rays, and electrons. X-rays and γ -rays are also known as photons or packets of energy and are used to treat most body sites where radiation is deemed efficacious. Other particles or forms of radiation, such as protons, neutrons, and heavier α particles, are less commonly used in radiation therapy except in select clinical situations. Protons, other heavy charged particles, and neutrons have a higher linear energy transfer coefficient when compared to high energy photons and therefore are more efficient at transferring or depositing their energy in tissue. Protons are used increasingly in the treatment of prostate cancers, choroidal melanomas, skull base and paraspinal tumors, and pediatric tumors. Neutrons have been used for salivary gland tumors, sarcomas, and prostate cancers. Protons are positively charged particles that can be accelerated in an electric field to high energies. The primary characteristic of a proton beam is its Bragg peak. The Bragg peak describes at what depth the majority of a proton's energy is deposited. Prior to the depth of the Bragg peak, only a very small amount of the proton energy is deposited. The Bragg peak depth is determined by the energy of the incident protons and covers only very small width of tissue at that depth. In order to cover more tissue, the energy of the incoming proton beam is varied. The net dose deposition results in a low entrance dose and a finely controlled width of treatment dose at depth. This makes proton treatments an excellent choice for the treatment of tumors adjacent to critical structures. Neutrons are relatively massive uncharged particles that can be generated by cyclotrons. Poor treatment geometry and dose distributions have limited the enthusiasm for neutron beam therapy (22).

X-rays and γ -rays are forms of electromagnetic radiation, similar to visible light, but with a much smaller wavelength, that is, greater energy. The difference between X-rays and γ -rays is only their respective origins. X-rays are derived from interactions in the atom that are outside the nucleus, typically by bombardment of the atom or target with high-speed electrons. This is the source of radiation produced by most modern radiotherapy treatment machines termed linear accelerators or linacs. Their name derives from acceleration of these electrons. γ -rays arise from a process within the nucleus of the atom called radioactive decay, which occurs in brachytherapy sources and cobalt (^{60}Co) teletherapy treatment machines. This type of electromagnetic radiation can penetrate several millimeters to centimeters of normal tissue in close proximity to tumors or tissues at risk. There is increased penetration as the energy of the gamma rays is increased. The X-rays produced by linear accelerators are much more penetrating than ^{60}Co gamma rays and are used to treat tumors or tissues at a distance from the linear accelerator such as deep within the pelvis or abdomen.

Electrons are small, negatively charged particles. Because of their inherent charge, these particles interact more strongly with the atoms found in tissue. Electrons will usually only penetrate a few millimeters to centimeters in tissue. Similar to photons, the higher the energy of the electron, the farther it will penetrate into the tissue. Electrons are used to treat tumors or tissues close to the skin surface such as superficial inguinal nodes and tumors of the skin, including vulvar cancers.

Regarding photon interactions with tissue, the dominant process at energies used in radiation therapy is termed the Compton effect (Fig. 12.12). The probability that a photon will interact with a target atom is inversely proportional to the energy of the incident photon and nearly independent of the atomic number of the target material. As a result, at the energies used in radiation therapy, termed megavoltage (MV), the absorbed dose in normal tissues is comparable to that in nearby bone. At much

FIGURE 12.12. Schematic drawing illustrating the process of the Compton effect. The incident photon interacts with one of the atom's outer electrons, and the energy is shared between the ejected electron and a scattered photon.

Source: From Purdy JA. Principles of radiologic physics, dosimetry, and treatment planning. In: Perez CA, Brady LW, eds. *Principles and Practice of Radiation Oncology*. 3rd ed. Philadelphia, PA: Lippincott-Raven Publishers; 1998, with permission.

lower energies, termed kilovoltage (kV), the absorbed dose would scale with the atomic number of the target with higher absorbed dose in bone compared to normal soft tissues.

At the second International Congress of Radiology in 1928, the basic unit of exposure, the roentgen (R), was defined (22). Although the original definition evolved over time, the fundamental idea remained the same. The roentgen is the amount of photon radiation that causes 0.001293 g of air to produce one electrostatic unit of positive or negative charge (esu). The value of 0.001293 g is the mass of 1 cc of air at a temperature of 0°C and a pressure of 760 mm Hg. The definition of the roentgen can also be expressed in other equivalent terms:

$$1 \text{ R} = 2.58 \times 10^{-4} \text{ C/kg air}$$

or, conversely, expressed in SI units, the unit of exposure is defined by:

$$1 \text{ C/kg} = 3,876 \text{ R}$$

Table 12.1 lists some basic units of radiation and radiation therapy, both in historic context and in terms of modern SI units. Kerma (kinetic energy release per unit mass) defines the transfer of energy from photons to directly ionized particles. These directly ionized particles, in turn, transfer some of their energy to the medium (usually tissue). This transfer of energy is defined as the absorbed dose to the medium from the radiation beam. The SI unit for kerma is joule per kilogram (J/kg) or gray (Gy). In a slightly confusing definition, the SI unit for absorbed dose is also joule per kilogram or gray. The term gray has replaced the previously used term "rad." Oftentimes the term centigray (cGy) is used. The cGy is equivalent to the rad and 1 gray equals 100 cGy.

Another rationale to think and communicate in SI units is that the roentgen was defined explicitly for photon interactions

Table 12.1 SI Units for Radiation Therapy

Quantity	SI Unit (Special Name)	Non-SI Unit	Conversion Factor
Exposure	C kg ⁻¹	roentgen (R)	1 C kg ⁻¹ ≈ 3876 R
Absorbed dose, kerma	J kg ⁻¹ (gray [Gy])	rad	1 Gy = 100 rad
Dose equivalent	J kg ⁻¹ (sievert [Sv])	rem	1 Sv = 100 rem
Activity	s ⁻¹ (becquerel [Bq])	curie	1 Bq = 2.7 × 10 ⁻¹¹ Ci

and not charged particles. Kerma and absorbed dose, although they have equivalence to the roentgen and exposure, can be defined equally for photons and charged particles.

RADIATION PRODUCTION

Radioactive Isotopes

As mentioned before, γ -rays are typically derived from radioactive isotopes, such as ^{60}Co . Electrons or beta particles also come from radioactive isotopes. In fact, most radioactive material produces a combination of photons (gamma rays) and electrons during the decay process. Radioactivity is the result of an atom changing its “energy” state, usually to a lower “energy” state, by the emission/absorption/internal conversion of photons or electrons in the atom. These processes result in disintegrations or radioactive decay, whereby the atom releases photons or electrons or both during the change in “energy” states. The release of these particles is a form of radiation (or energy) that can be used to irradiate tissues. The absorbed dose resulting from this radiation depends on the energy and particle type as mentioned above, as well as the tissue in which it interacts.

Radioactivity, or activity, is denoted by the symbol A and is defined as the number of disintegrations per unit of time. The following relationship defines activity, the decay constant, and ultimately the half-life for a radioactive material:

$$A = N/t = \gamma N$$

This equation is solved using an exponential solution:

$$A = A_0 e^{-\lambda t}$$

where A is the initial activity, λ is the decay constant, and t is some unit of time later. Other important units for radioactivity and radioactive decay are the half-life, $T_{1/2}$, and the average life, T_a . The half-life is the amount of time necessary to reduce the original amount of material by half. This is also equivalent to reducing the original activity by half. $T_{1/2}$ is related to the decay constant by $T_{1/2} = 0.693/\lambda$. The average life represents the period of time that a hypothetical source would need, if it retained its original activity for a fixed period of time (T_a) before suddenly decaying to zero activity, to produce the same number of disintegrations over an infinite amount time by the same source if it decayed exponentially. T_a is related to the decay constant and the half-life by $T_a = 1/\lambda = 1.44 T_{1/2}$.

Radioactive isotopes can occur naturally or be created artificially. Artificially created isotopes are usually created by neutron bombardment of otherwise stable isotopes. The resulting interactions produce atoms that are inherently unstable and will decay to a more stable form with a predictable half-life, releasing energy or radiation through this decay. Naturally occurring radioactive isotopes originally come from one of three standard series—the uranium series, the actinium series, and the thorium series—so named because of a dominant radioactive isotope in each series. In general, the higher the atomic number, the more likely an isotope will be radioactive. Table 12.2 lists many of the more common radioactive isotopes and their physical properties. For gynecologic cancers, use of radium 226 (^{226}Ra) sources is now historic. Though cost-effective because of its long half-life (1,622 years), radium releases a by-product, radon gas, if

Table 12.2 Physical Properties and Uses of Brachytherapy Radionuclides

Element	Isotope	Energy (MeV)	Half-Life	HVL-Lead (mm)	Source Form	Clinical Application
Obsolete Sealed Sources of Historic Significance						
Radium	^{226}Ra	0.83 (avg)	1,626 years	16	Radium salt encapsulated in tubes and needles	LDR intracavitary and interstitial
Radon	^{222}Rn	0.83 (avg)	3.83 days	16	Radon	Permanent interstitial; temporary molds

LDR, low-dose rate; HDR, high-dose rate.

the integrity of the source capsule is compromised. This could require closure of hospital wards due to radon gas contamination. Cesium 137 (^{137}Cs) has replaced radium as a safer yet effective radioisotope. Less shielding is required for cesium than radium, and there is no risk of radon gas leakage. With a half-life of 30 years, it is also cost-effective due to the infrequent need for replacement. Cesium can be used clinically for years without replacement, but the treatment duration must be adjusted to allow for radioactive decay (23). It is typically used for low-dose-rate gynecologic brachytherapy in tandem and ovoid and cylinder applicators. Iridium 192 (^{192}Ir) comes in various activities and can be used for interstitial and intracavitary gynecologic implants. Its half-life of 74.2 days requires frequent replacement and, typically, this is custom ordered individually for each implant rather than stored in the radiation oncology department like ^{137}Cs sources. High activity ^{192}Ir (^{10}Ci) sources are used for high-dose-rate brachytherapy and are replaced every 3 months, and lower activity ^{192}Ir sources are used for LDR brachytherapy.

Linear Accelerators

Linacs are another method of producing radiation for treatment of malignancies. Linacs can produce both photon and electron beams of different energies depending on their construction. The principles behind a linac involve accelerating an initial beam of electrons across a variable electric field. The greater the strength of the electric field, the more energetic the electron beam. This electron beam can be adjusted to control its shape and intensity before delivery to the patient. Alternatively, the electron beam can be directed to a tungsten target. The electron-target interaction creates a forward scattered photon beam or X-ray. The resulting photon beam can then be modified by the machine using filters and collimators to produce the desired radiation field shape.

Photon beams of different energies have a different absorbed dose pattern within tissues. This pattern is normally characterized as a percent depth dose or variation of dose as a function of depth within tissue, as shown in Figure 12.13 and Figure 12.14, and by dose profiles, or variation of dose as a function of lateral distance at a given depth (Fig. 12.15). The key feature in all of the figures is that higher-energy photons deposit dose at greater depths. Because of the way dose is deposited and absorbed in tissue, the higher the photon energy, the less dose is deposited at shallow depths toward the surface of the patient. This is called “skin sparing” and is a characteristic of high-energy photons. In fact, the higher the photon energy, the deeper the point at which the maximum absorbed dose is deposited. After this D_{max} , the absorbed dose decreases because the photon beam is attenuated by the tissues through which it passes.

Figure 12.16 shows a simplified drawing of a linac. The gantry (or part of the linac where radiation exits the machine) can rotate 360° around the patient on the treatment table. The table can also be rotated about the vertical axis of the radiation beam. This combination of angles allows the radiation to be directed to almost any part of a patient's body.

Modern linacs come equipped with multileaf collimators (MLCs) and asymmetric jaws to control the shape of the radiation beam directed before it reaches the patient (Fig. 12.17). Prior to asymmetric jaws and MLCs, photon beam shaping was achieved using poured blocks mounted below the lowest machine jaws. The composition and thickness of the poured block material are sufficient to block more than 97% of the radiation, allowing less than 3% of the radiation to penetrate the block and reach the patient. MLCs have mostly replaced poured blocks, but in some cases, poured blocks are still necessary for detailed field shaping.

MLCs are small (projected size at the patient ~1 cm), adjustable collimators built into the linac gantry that work together to create a shaped opening mimicking the effects of a poured block. Because each MLC is adjustable, a new field shape can be “programmed” into the gantry without the necessity of pouring a different block for every treatment field. With the advent of computer-controlled motion of the MLCs, the radiation field can be further controlled to produce an intensity-modulated

radiation therapy (IMRT) treatment. In IMRT treatments, the MLCs are used to create many small fields of radiation within a larger treatment field. By opening and closing these small fields, the intensity at any point within the large field can be modulated to give more or less dose to the tissues directly exposed to the radiation. At one gantry angle, the IMRT field may need to spare a critical normal structure but still treat the target to a lower dose, while in another gantry angle, that same critical structure may be out of the field and the target can get a higher intensity to compensate for the lowered intensity in the first field. This adaptability allows the radiation treatment planner to create and deliver very complex treatment fields that improve target coverage while attempting to spare normal tissues. In practical terms, IMRT treatment plans are an improvement of the more conventional three-dimensional (3-D) conformal treatment plans. 3-D conformal treatment plans use fewer fields to achieve nominal coverage of the treatment target. At each gantry angle, the radiation is either hitting the target/normal tissue or not with a simple shaped treatment field. Normal tissues may be impossible to spare relative to adjacent targets. IMRT treatment plans may use similar gantry angle setups, but with the additional intensity modulation, the IMRT fields can create a complicated dose distribution within the patient. In some cases, where the normal tissues are relatively far from the target tissues, there may be no benefit or rationale for the more complex IMRT treatment plan compared to 3-D conformal treatment plans. In cases where the proximity of normal tissues and target vary across a field and between gantry angles, IMRT may prove the more efficient treatment plan to protect normal tissues while focusing dose onto the target (Fig. 12.18).

IMRT is being used in the treatment of gynecologic cancers. The setting where it may be the most helpful and the most widely accepted is postoperatively for select endometrial and cervical cancer presentations (24,25). Results of the RTOG 0418 study showed a decrease in both acute and late toxicity in the postoperative setting in patients with either cervical or endometrial cancers (26). In this setting, there is often a significant amount of small bowel in the pelvis that can be avoided to a greater degree with IMRT than 3-D conformal radiation techniques (Fig. 12.19). Bone marrow sparing can also be improved over a 3-D conformal approach (27). Bladder and rectosigmoid doses can also be reduced. Margin sizes around the target and bladder and rectal filling are important considerations, as are immobilization techniques when using IMRT. Target delineation and normal organ delineation are extremely important when using IMRT. What is not defined is either not adequately treated or spared (28). RTOG 0418 defined parameters for contouring of targets and normal organs, margin size, and dose volume constraints in the postoperative setting in early cervical or endometrial cancers (29). An online atlas available on the RTOG website was developed to improve consistency between multiple contouring physicians and continues to be used to guide in target delineation even though the protocol has been completed (30). This same atlas has been used in GOG studies, which include IMRT techniques with minor modifications over time. A normal tissue-contouring atlas is also available on the RTOG website (31). Other atlases are available to guide radiation oncologists in defining these structures of interest (32,33). When using IMRT to treat the intact uterus, bladder filling can have even more influence on the position of the uterus, and the vagina and uterus can move several centimeters as a result (34,28). Stool in the rectosigmoid can also cause movement of the adjacent pelvic organs and alter the dose distribution in the rectosigmoid.

Where there is more controversy is in the use of IMRT for intact cervical cancer. Use of IMRT in the definitive management of cervical cancer has been piloted at the University of Chicago (35). In their series, IMRT has reduced both acute and late gastrointestinal (GI) toxicities and helped to spare bone marrow during treatment (35). Other series have shown a similar decrease in toxicity with use of IMRT (36). There is concern in this setting about organ motion relative to the dose distribution. This can be due to bladder or rectosigmoid filling, disease regression, or sporadic motion (37–40). Careful attention to organ filling, patient immobilization, and margin size can help to minimize such motion which could compromise target and normal organ doses (28). Daily CT imaging prior to treatment can also help to assess for this motion and adapt the treatment plan as needed (41,39). A consensus guideline has been published to begin to define the most appropriate clinical target volume for intact cervical cancer with recognition of the significant uncertainties caused by motion in this setting (42). Practice guidelines for IMRT have been published by ASTRO and ACR (43,44). Use of IMRT for extended field irradiation to treat the pelvic and paraaortic regions, is successfully implemented to decrease dose to the small bowel, kidneys, liver, spinal cord, and bone marrow (Fig. 12.20). Selective boosting of gross nodal disease may allow for safer dose escalation (37,39,45–47). IMRT techniques have also been used for whole abdominal irradiation to reduce doses to the gastrointestinal tract, liver, kidneys, and bone marrow and to increase dose to the peritoneal surfaces and lymph nodes (48,49) as well as for vulvar cancers to help spare the upper femur as well as the small bowel and bone marrow (50).

A pivotal treatment technique for the success of IMRT is image-guided radiation therapy (IGRT) (41,39,51). Historically, treatment setups were verified by orthogonal radiographs and treatment fields by port films or X-rays of the treatment fields superimposed on the patient. Modern linacs have added on-board imaging (OBI) that allows the treatment fields to be recorded electronically at every treatment setup using an

electronic portal-imaging device (EPID). By comparing computer generated radiographs (DRRs or digitally reconstructed radiographs) with the actual patient images, discrepancies in field shape and patient setup can be corrected before the delivered treatment. This type of corrective behavior before treatment is the foundation of IGRT. The latest variation on IGRT is the addition of computed tomography (CT) scanners within the linear accelerator to verify more completely the correct alignment of the patient on the treatment table prior to treatment. CT scans are obtained prior to each treatment. In some cases, the CT scans are constructed based on the photon beams (MV) that will be used for treatment. In other cases, a different photon source (kV) is used to reconstruct the CT scan. Because cone beam CT (CBCT) or megavoltage CT (MVCT) uses a high-energy photon beam to gather the information for reconstruction, the image quality suffers because of poor soft-tissue contrast. KVCT or normal CT images, because they use a lower energy photon beam to reconstruct the patient image, have better soft-tissue contrast, but are prone to distorting artifacts from

high-density objects within the patient, that is, hip prostheses. In either case, the CT image at the time of treatment and its corresponding isocenter location are compared to the treatment planning CT and isocenter for agreement. Adjustments for rotation, lateral, vertical, and longitudinal discrepancies are made prior to treatment. The intent of these IGRT treatments is to improve the accuracy of the treatment setup on a daily basis relative to the original treatment plan. This enables decreasing the size of the radiation fields, as there is not as much need for a large margin on the target, which can decrease normal tissue irradiation and even allow for dose escalation to the target. Guidelines for use of IGRT have been published by ASTRO and ACR (52). On-line MR imaging has recently been added to radiation treatment machines and will allow for better soft-tissue resolution of intact cancers such as cervical or vaginal cancers to guide treatment accuracy.

Intensity-modulated arc therapy has been used to deliver IMRT. Tomotherapy is one form of arc therapy. Tomotherapy (Fig. 12.21) is a special type of linac/CT combination (51).

TomoTherapy units were the first commercially available treatment machines that directly combined CT (MVCT in this case) with highly complex MLCs to deliver IMRT using IGRT. Each day, the patient receives an MVCT, a comparison using 3D fusion to the original treatment plan is made, adjustments to the patient position are made, and IMRT treatment is delivered without the patient needing to change machines. Corrections to the delivered dose can even be modeled based on the patient's current anatomy as visualized by the MVCT built into the TomoTherapy machine. Excellent clinical outcomes have been published with rotational therapy (53). Other linacs are using variation of arc therapy to perform IMRT delivery. Varian (RapidArc®) and Elekta (VMAT) controls gantry speed, aperture shape, and dose rates to generate their arc therapy treatments, a form of volumetric modulated arc therapy (VMAT). Both use the same principle of modulating the beam aperture while the gantry is moving in arc to minimize the time and monitor units while improving dose conformity. In addition to photon beams, many linacs provide the option to treat patients with electron beams of various energies (e.g., 4 to 21 million electron volts [MeV]). Compared to photon beams, electron beams have different depth dose and dose profiles (Fig. 12.22), when electrons, even at the same energy as photons, do not penetrate as far as photons do within tissues. While electron depth doses have a D_{max} that increases with increasing energy, unlike photons, the higher the electron energy, the higher the surface dose to tissue, that is, loss of “skin sparing.” Electrons have been used in the treatment of vulvar and other cancers that involve the inguinal lymph nodes. Great care has to be taken when using electrons in this setting as the inguinal lymph nodes can be very

deep in women with higher body mass indices (BMI) and will under dose nodes at a depth >3 cm. This resulted in an increased risk of inguinal failures in GOG study (54,56,55). Electrons can be used to treat vulva in patients with close or positive vulvar margins or in combination with higher-energy beams to treat the inguinal nodes in lower BMI patients.

Simulation

The conventional simulator used in radiation oncology departments reproduces all the gantry, collimator, and table rotations used in a linac treatment, and therefore “simulates” the actual treatment. Instead of a therapy (MV) photon beam, the conventional simulator uses a diagnostic (kV) photon beam to simulate the treatment beam. Previously, the conventional simulator (Fig. 12.23) allowed the radiation oncologist to determine beam direction and treatment fields that would be needed for a radiotherapy treatment based on X-ray fluoroscopy. The radiographic visualization of internal structures allowed special shielding (poured blocks) to be constructed. All the geometric parameters of the conventional simulator are nearly identical to the actual treatment linacs. The intersections of the gantry rotation axis, collimator rotation axis (the machine isocenter), and patient location are identified and marked on the patient's skin with removable ink or a permanent series of tattoos. These marks

FIGURE 12.20. **A:** Contours of enlarged paraaortic nodes with margin are shown in close proximity to small bowel. **B:** IMRT plan for extended field irradiation in axial, coronal, and sagittal projections.

facilitate the reproduction of the same clinical setup for the patient each day of treatment. Hard-copy radiographs can also be used to document the expected treatment fields for comparison with port films obtained on the treatment linac.

CT-based simulators (“CT Sims”) have largely replaced conventional simulators in most radiation oncology departments. CT Sims (Fig. 12.23) combine a diagnostic CT scanner with a software package that allows for the simulation of the patient setup in the virtual world of the computer. All of the necessary gantry angles and table angles are modeled in the computer. Computer-controlled room lasers tied into the CT Sim software allow the simulator therapist to identify the treatment isocenter in a fashion similar to the conventional simulator. DRRs are created for later comparison to actual treatment images. The treatment isocenter and the full CT images can then be transferred to the computer planning system for further treatment planning. Some departments are also equipped with MR or PET scanners for treatment planning. Fusion of CT images with PET or MR images enables CT-based treatment planning with the benefit of improved tumor definition with PET or MR to reduce margin size or increase dose (36).

Computerized Dosimetry

In a modern radiotherapy department, computers are necessary to accurately calculate the absorbed doses to tissues. These absorbed doses within tissues are termed isodoses, or lines of the same dose. To initiate this process, CT images are acquired of the area of interest at a pretreatment planning session or simulation. These scans are typically obtained on the CT simulator. Treatment targets such as pelvic/para-aortic lymph nodes, the uterus, or vagina are identified through contouring on these images, as are normal tissues such as the rectosigmoid, bladder, large and small bowel, kidneys, stomach, and spinal cord. Dose goals are identified for the targets and normal tissues. A dosimetrist uses this information to design the radiation treatment plan. Treatment beams are planned and the resulting dosimetry is reviewed by the treating physician and a physicist and altered as needed to best address the tumor and avoid the normal organs and tissues. In order for a computer treatment planning system to do all this, the depth dose and dose profiles for all of the treatment beams (photons and electrons) must be accurately entered into the planning system.

There are varying complexities of treatment plans that might be used. For simple targets, such as metastatic cancer to the spine, a simple single field or parallel opposed, two-dimensional (2-D) plan might be all that is required. Complexities of internal anatomy and external surface contours can be ignored while still successfully delivering a palliative treatment plan to the patient. More complicated target definitions might require specific and accurate knowledge of adjacent internal anatomy and the details of the patient’s surface in order to accurately deliver a successful treatment plan. In these cases, a 3-D conformal treatment plan is developed. In still more complicated target/normal tissue regions, IMRT treatment planning might be required in order to give sufficient dose to the target while minimizing the dose to an adjacent normal tissue. The goal for most treatment plans is to treat the target to a specified dose while minimizing dose to adjacent normal tissues.

In all of these examples, the word “target” is used. The goal is to encompass the target with the desired dose. Targets are more formally defined in ICRU 50 (57). Figure 12.24 illustrates the gross target volume (GTV), the clinical target volume (CTV), the planning target volume (PTV), and the treated volume. Each of the target or tumor volumes is larger than the previous target volume by some margin. The CTV includes all of the GTV plus possible microscopic extensions. The PTV includes all of the CTV plus a margin to account for possible geometric uncertainties of the patient or treatment margin. The irradiated volume includes

all of the PTV plus any margins that might be included in the treatment plan to provide minimum dose coverage to the PTV.

Brachytherapy Principles

Brachytherapy is a term with Greek roots where “brachy” means “short distance.” With brachytherapy, a highly concentrated dose of radiation is delivered to immediately surrounding tissues within millimeters to several centimeters of the applicators that carry the radioactive sources (58). This allows for a high dose of radiation to be delivered to closely approximated tumor and to relatively spare surrounding normal tissues such as the rectosigmoid, bladder, and small bowel. This is in comparison to teletherapy, where “tele” means “far distance” and refers to external beam irradiation where the radiation source is at a

greater distance from the patient (~100 cm) than with brachytherapy. With external beam irradiation, the tumor and/or tumor bed are typically irradiated along with adjacent tissues at risk such as lymph nodes. External beam irradiation typically is much more penetrating than brachytherapy unless electron beam external irradiation is used. With electron beam therapy, superficial structures such as the skin and or superficial lymph nodes are optimally treated unlike the deep abdominopelvic tissues, which are best irradiated with the penetrating photons produced by a linear accelerator.

There are different types of brachytherapy or radioactive implants (58). Temporary implants are used most frequently and are categorized as interstitial or intracavitary. With interstitial brachytherapy, the radioactive sources are transiently inserted into tumor-bearing tissues directly through placement in hollow needles or tubes. With intracavitary brachytherapy, radioactive

sources are placed into naturally occurring body cavities or orifices such as the vagina or uterus using commercially available hollow applicators such as a vaginal cylinder or tandem and ovoids. Temporary surface applications or plesiotherapy for ophthalmic or skin tumors and intraluminal applications in the esophagus, bronchus, and bile duct are other possible approaches. Permanent interstitial implants entail insertion of radioactive seeds (iodine 125 [^{125}I]; gold 198 [^{198}Au]; palladium 103 [^{103}Pd]) directly into tumor-bearing tissues to emit radiation continuously as they decay to a nonradioactive form (58). Radioactive sources are also sealed or unsealed, referring to whether they are solid (^{137}Cs ; ^{192}Ir) or liquid radioisotopes (phosphorus 32 [^{32}P]). The most common sealed radioactive sources used for gynecologic brachytherapy are ^{192}Ir and ^{137}Cs . Historically, unsealed radioactive sources such as ^{32}P have been used to treat the entire peritoneal cavity in ovarian cancer. The limitation of this source was that the beta rays emitted penetrated only a distance of 3 mm, making it useful only for

patients with microscopic or very thin residual tumor deposits following debulking.

Dose rate is also an important variable in brachytherapy. Traditional LDR irradiation has been used for decades in gynecologic cancers using ^{226}Ra and ^{137}Cs sources for intracavitary insertions and low activity ^{192}Ir sources for interstitial insertions. HDR brachytherapy has gradually been introduced over the last several decades and entails the use of a highly radioactive (^{10}Ci) ^{192}Ir source. There are several definitions for the dose rates used in brachytherapy. The ICRU 38 classifies LDR as 0.4 to 2 Gy/hr, MDR (medium dose rate) as 2 to 12 Gy/hr, and HDR as >12 Gy/hr (59). More standard ranges for LDR are 40 to 100 cGy/hr, and for HDR 20 to 250 cGy/min, which is 1,200 to 15,000 cGy/hr. Pulsed dose rate (PDR) is increasingly popular with the scarcity of available new ^{137}Cs sources. Rather than using a high-activity ^{10}Ci ^{192}Ir source with short dwell times as in HDR, PDR uses a medium-strength ^{192}Ir source of 0.5 to 1.0 Ci with dose rates of up to 3 Gy/hr. The radiation with PDR is typically delivered in

a “pulsed” method over only 10 to 30 minutes of each hour as opposed to LDR techniques, which deliver 30 to 100 cGy/hr continuously over several days (60,61). PDR delivers the same total dose over the same total time at the same hourly rate as LDR, but with an instantaneous dose rate higher than LDR. PDR brachytherapy was developed to combine the isodose optimization of HDR brachytherapy with the biologic advantages of LDR.

The term “afterloading,” whereby an unloaded applicator is inserted first and the radioactive sources introduced later, was popularized by Henschke (62). Nearly every modern brachytherapy exploits afterloading. An ideal implant is established with the appropriate applicator before being loaded with the radioactive sources. This sequence allows for more careful and accurate applicator placement than inherent to earlier “hot loaded” applicators, which were placed in the operating room preloaded with radium. Radiation exposure to medical personnel is reduced and exposure of operating room personnel is totally eliminated. Remote afterloading, which eliminates all personnel exposure, entails the use of a computer-driven machine to insert and retract the source(s), which are attached to a cable. During treatment, the source is transported from its shielded safe to the patient's applicators via a transfer tube. Sources are retracted automatically whenever visitors or hospital personnel enter the room. With modern remote afterloading techniques, a single cable-driven radioactive source is propelled through an array of dwell positions in needles, plastic tubes, or intracavitary applicators within an implanted volume. Through computerized dosimetry, the source stops for a specified duration at a preselected number of locations during its transit, delivering a specified dose to a defined volume of tissue. This dose may be delivered rapidly in a large fraction, as in the case of HDR brachytherapy, or a series of small “pulsed doses” delivered at a given frequency over a period of days, as in PDR brachytherapy (60). Typically, these treatment units are housed in shielded rooms in the hospital (LDR or PDR) or the radiation oncology department (HDR) to further eliminate radiation exposure (58).

Radiation Protection

The amount of radiation that a person other than patients under treatment can receive is governed by state and federal

regulations. The actual values depend on whether the person is considered part of the general public or an occupationally exposed worker. These values can change with different regulations. The National Council on Radiation Protection and Measurements (21) set the following recommendations for limits on exposure to ionizing radiation:

Public exposures <1 mSv or 0.1 rem annually

Occupational exposures <50 mSv or 5 rem annually

Additionally, NCRP Report #91(21) placed limits on embryo-fetus exposures:

Total dose limit <5 mSv or 0.5 rem

Dose equivalent limit in 1 month <0.5 mSv or 0.05 rem

These recommended limits were adopted by the Nuclear Regulatory Commission (10 CFR 20, Standards for Protection against Radiation).

Linacs produce radiation using electrical power. Once the linac is turned “off,” there is little, if any, radiation exposure risk to staff. Radioactive isotopes, used most often for brachytherapy, however, do not have an “off” switch. They are always undergoing radioactive decay with the resultant radiation production of X-rays, γ -rays, electrons, and other particles.

Radiation safety is an important focus for patient and health care workers. All hospitals that house radioactive sources or linear accelerators will have a special department termed radiation safety. Radiation personnel are responsible for monitoring radiation exposure in hospitals and clinics. All health care workers exposed to radiation must wear badges that track radiation exposure. There are three words that encompass all of the important aspects of radiation safety and protection: time, distance, and shielding. All three can be used to reduce radiation exposure. The dose delivered to a target from a radioactive source is directly proportional to the amount of time the target is exposed to the radioactive source (63). The dose delivered to a target is inversely proportional to the square of the distance from the radioactive source double the distance and the dose is reduced by a factor of four:

$$\text{Dose} \sim \text{time}$$

$$\text{Dose} \sim 1/r^2$$

This is the inverse square rule. The relationship between shielding and absorbed dose is more complicated. The simplest explanation is that the absorbed dose is reduced in an exponential relationship to the physical amount of shielding. The exact relationship (μ) depends on the energy of radiation and the specific material, such as concrete or lead, used to provide the protection. More material (x) means more protection. Less energy means more protection for the same thickness (x) of material:

$$\text{Dose} \sim e^{-\mu x}$$

Minimizing time, maximizing distance, and maximizing shielding will reduce one's absorbed radiation dose. Fortunately, there is relatively little exposure to radiation for most health care providers. The linear accelerators in radiation oncology are strategically located and shielded to minimize radiation to anyone other than the treated patient. Many brachytherapy insertions are typically performed with remote afterloading to minimize exposure, and often outpatient brachytherapy can be realized because of HDR techniques. This takes the patient off the hospital ward and thereby avoids exposure to the health professional caring for inpatients. The shielded rooms in the radiation oncology department protect the attendant staff from exposure as well.

CLINICAL APPLICATIONS

Historical Background

The use of radiation in the treatment of gynecologic cancers has a rich history. Roentgen rays were used externally as early as 1902 to treat cervical carcinoma and “radium rays” in 1906. In Europe, the use of intracavitary radium was reported in 1903 for the treatment of inoperable uterine cancers (64). In 1913, Robert Abbe was the first to report a true cure with a patient alive and well after 8 years of follow-up (65). In those early years, there was little knowledge of the biologic effects of radiation on the normal and tumor tissues. Typically, a uterine tandem was used alone without vaginal colpostats. There was little understanding of the dose distribution in the tumor and surrounding normal tissues, and implant duration, and thereby dose, was entirely empirical. Complications and failures were common.

Brachytherapy Systems for the Treatment of Cervical Cancer

Intracavitary brachytherapy for cervical carcinoma was profoundly impacted by the development of various “systems” that attempted to combine empiricism with a more scientific and systematic approach. A dosimetric system refers to a set of rules concerning a specific applicator type, radioactive isotope, and distribution of the sources in the applicator to deliver a defined dose to a designated treatment region (59). Within any system, specification of treatment in terms of dose, timing, and administration is necessary to implement the prescription in a consistent manner. Three systems were developed in Europe, including the Paris system, the Stockholm system, and the Manchester system (66,67,68). The Manchester system principles are an integral part of modern brachytherapy (68).

The Manchester System

The Manchester system was developed in 1932 by Tod and Meredith (68,69,70), and was later modified in 1953 (71) at the Holt Radium Institute. It standardized treatment with predetermined doses and dose rates directed to fixed points in the pelvis. The fixed points A and B were selected on the theory that the dose in the paracervical triangle impacted normal tissue tolerance rather than the actual doses to the bladder, rectum, and vagina. The paracervical triangle was described as a pyramidal-shaped area with its base resting on the lateral vaginal fornices and its apex curving around with the anteverted uterus. “Point A” was defined as 2 cm lateral to the central canal of the uterus and 2 cm from the mucous membrane of the lateral fornix in the axis of the uterus (Fig. 12.25). It often correlates anatomically with the point of crossage of the ureter and uterine artery and was taken as an average point from which to assess dose in the paracervical region. “Point B” was located 5 cm from midline at the level of point A and was thought to correspond to the location of the obturator lymph nodes. To achieve consistent dose rates, a set of strict rules dictating the relationship, position, and activity of radium sources in the uterine and vaginal applicators was devised. The amount of radium would vary based on ovoid size and uterine length such that the same dose in roentgen would be delivered to point A regardless of the size of the patient or the size and shape of the tumor, uterus, and vagina. The vaginal ovoids were available in three sizes: small (2.0-cm diameter), medium (2.5-cm diameter), and large (3.0-cm diameter) and were preloaded or “hot loaded” with radium.

FIGURE 12.25. The Manchester system. Definitions of points A and B in the classical Manchester system are found in the text. In a typical application, the loading of intrauterine applicators varied between 20 and 35 mg of radium and between 15 and 25 mg of radium for each vaginal ovoid. The resultant treatment time to get 8,000 R at point A was 140 hours. Source: From Meredith WJ, *Radium Dosage: The Manchester System*. Edinburgh, UK: Livingstone, 1967, with permission.

The amount of radium per ovoid varied by size to get a uniform dose rate at the ovoid surface. It was recommended to use the largest ovoid size possible and place the ovoids as far laterally as possible in the fornices to carry the radium closer to point B and increase the depth dose. Vaginal packing was used to limit the dose to the bladder and rectum to <80% of point A. Two intracavitary applications of 72 hours with a 4- to 7-day interval between them were given to deliver a dose of 8,000 R at 55.5 R/hr to point A and 3,000 R to point B. External beam irradiation with a midline block in place was later used to deliver a total cumulative dose of 6,000 R to point B.

The Manchester system underlies contemporary intracavitary techniques and dose specification. With current LDR applications using cesium rather than radium, it is considered standard to have a point A dose rate of 50 to 60 cGy/hr and to deliver a total dose of 85 Gy to point A and 60 Gy to point B when combined with external beam therapy while limiting the normal tissues to <80% of the point A dose.

The Fletcher (M.D. Anderson) System

The Fletcher system was established at M.D. Anderson Hospital in the 1940s (72). The Fletcher applicator was subsequently developed and remains an integral part of gynecologic brachytherapy (Fig. 12.26) (73). The initial dosimetric work at M.D. Anderson was done prior to the development of computerized dosimetry in the 1960s (74). As in the Paris system, milligram-hours (mg-hr) were used for dose prescription with the premise that with any geometric arrangement of specified sources, dose at any point is proportional to the amount of

FIGURE 12.26. Fletcher Suit Delclos low-dose-rate applicators. Left to right: Afterloading colpostats, mini ovoids, tandems, cylinders, and source inserters.

radioactivity and the implant duration. Though previous systems (Paris and Stockholm) had used mg-hr, clinical experience alone determined the amount of radium tolerable to the tissues. Fletcher predicted that better results and less morbidity could be obtained if knowledge of the energy absorbed at various points in the pelvis (“measured data”) such as the bladder and rectum and pelvic lymph nodes could be determined (75). According to Fletcher, a dosimetric approach should meet the following requirements: (a) ensure that the primary disease in the cervix and fornices and immediate extensions into the paracervical triangle are adequately treated; (b) guide treatments in such a way that the bladder and rectum are not overdosed (respect mucosal tolerance); and (c) determine the dose received by the various lymph node groups. Individualization to fit the anatomical situation was an essential aspect of this system (76).

The primary prescription parameter in the Fletcher system was tumor volume, and prescription rules were based on maximum mg-hrs and maximum time, taking into account the total external beam dose and the calculated sigmoid dose. An application was left in place until either of these two maximums was reached. Large mg-hr implants were halted by the mg-hr prescription while smaller mg-hr implants were terminated by time. A set of maxima of mg-hrs was established for combinations with external irradiation, which were published in tables (77,78). Standardized source arrangements and limits on the vaginal surface dose and mg-hrs were all used to help specify treatment.

Despite a more elaborate dosimetry system, the Fletcher system combined many elements of the Paris and Manchester systems, including using the largest size ovoid possible positioned as far laterally and cephalad as possible to give the highest tumor dose at depth for a given mucosal dose. By using a larger ovoid, the radium-mucous membrane distance was increased, allowing a greater increase in the total number of mg-hrs and a greater volume of adequate irradiation (72). The Fletcher colpostats were actually a further evolution of the Manchester ovoids and were made with the same diameters of 2, 2.5, and 3 cm but were more cylindrical than Manchester “ovoids” and were attached to handles, with shielding in the direction of the bladder and rectum. Initially these were preloaded with radium, but later an afterloading model was developed and loaded instead with ^{137}Cs (79,80). Recommended loadings were 15, 20, and 25 mg of radium for the 2-, 2.5-, and 3-cm colpostats,

respectively, and 5 to 10 mg for the mini-ovoids (79). Like the earlier systems, it was also recommended to use the longest tandem available and load the tandem so that sources reached the uterine fundus to give an adequate distribution in the lower uterine segment and paracervical areas and to increase the dose to the obturator lymph nodes. Additionally, a high position of the applicator in the pelvis and a wide separation of the ovoids were thought to increase the dose to the pelvic wall (72,81). Tight packing was also recommended to displace the system upward and centrally and to decrease the dose to the bladder and rectum (72). Recommended tandem loadings were usually 15–10–10 mg of radium with the amount of radium in the tandem usually greater than that in the ovoids (76). The distal source in the tandem was to be positioned to produce an even pear-shaped dose distribution with no drop in dose rate between the tandem and ovoids, without excessive overlap that would cause a hot spot on the adjacent bladder or rectal mucosa. With the ovoids well positioned, this was usually accomplished by placing the physical end of the distal source at or a few millimeters beyond the external os of the cervix. A 10-mg protruding source was recommended if the vaginal ovoids were separated by more than 5 cm or displaced caudally, with each ovoid then decreased by 5 mg.

A careful review of implant films was outlined (Figure 12.27). It was recommended to keep the tandem in the axis of the pelvis, equidistant from the sacral promontory and pubis and the lateral pelvic walls to avoid overdosage to the bladder, sigmoid, or one ureter. The tandem was recommended to bisect the ovoids on the AP films and bisect their height on the lateral films (82). The flange of the tandem was to be flush against the cervix and the ovoids surrounding it, verified by confirming the proximity of the applicators to radio-opaque cervical seeds. Radio-opaque vaginal packing was used to hold the system in place and displace the bladder and rectum. Scrutiny of implant films prior to treatment remains an important tenant of brachytherapy. Two or more intracavitary insertions were thought to make more efficient use of the inverse square law such that the second and third implants would deliver intense radiation to the tumor periphery because of interval tumor regression. A recent retrospective review of implant geometry has confirmed the consistency of the M.D. Anderson approach and the good outcomes achieved when attention is paid to applicator position in the pelvis (83).

The current M.D. Anderson approach to treatment specification reflects a policy of treating advanced cervical carcinoma to normal tissue tolerance (84). This includes integrating standard loadings and mg-hrs with calculated doses to the bladder, rectum, sigmoid, and vaginal surface. The activity in the ovoids is limited by the vaginal surface dose, which is kept below 140 Gy. Calculated bladder and rectal doses are noted and are sometimes used to limit the duration of the intracavitary system, with the combined external beam and implant doses for the bladder kept at <75 to 80 Gy and for the rectum at <70 to 75 Gy. Mg-Ra-eq-hrs are usually limited to 6,000 to 6,500 after 40 to 45 Gy external beam. Though mg-hrs have usually been used to guide and report doses at M.D. Anderson, recent retrospective reviews have also reported point doses, though these have not been used to plan or prescribe treatment. With the implant loadings and durations outlined by Fletcher, typical dose rates at point A are approximately 57 cGy per hour and vaginal surface dose rates are 100 cGy/hour (83,85). The median doses to point B and to the International Commission on Radiation Units & Measurements (ICRU) rectal and bladder reference points averaged 28%, 59%, and 60% of the point A doses, respectively. The median total dose to point A from external beam and intracavitary irradiation was 87 Gy, and the median doses to the bladder and rectum were 68 and 70 Gy. The total dose delivered to the vaginal surface was limited to 120 to 140 Gy or 1.4 to 2.0 times the point A dose. These total doses to

FIGURE 12.27. Ideal position of tandem and ovoid applicator on an AP radiograph **A**: and a lateral radiograph **B**: Note the metallic seeds inserted into the cervix.

point A and the vagina, bladder, and rectum are used as contemporary guidelines for determining implant duration and, therefore, dose.

Point A Redefined

The failure of localization radiographs to show the surfaces of the ovoids made implementation of the initial definition of point A difficult. The definition of point A was modified in 1953 to be “2 cm up from the lower end of the intrauterine source and 2 cm laterally in the plane of the uterus, as the external os was assumed to be at the level of the vaginal fornices” (Fig. 12.28) (71). This definition of point A is currently used at many institutions (86,87). A seed or marker ball placed near the exocervix and coincident with the tandem flange is used to identify the exocervix on the localization films. This definition, however, becomes problematic when the cervix protrudes between the ovoids (Fig. 12.29). This causes a resultant increase in dose rate at point A because point A lies in the higher dose “bulge” around the ovoids (81). The variation of point A often occurs in a high-gradient region of the isodose distribution. A consistent location for dose specification should fall sufficiently superior to the ovoids where the dose distribution runs parallel to the tandem (Fig. 12.30) (88,89). In patients with deep vaginal fornices, reverting to use of the ovoid surface rather than the exocervix can help to solve this problem (88,89).

Limitations of Brachytherapy Systems: Point A

It has become clear over time that points A and B are not anatomic sites. The actual specification is related to the position of the intracavitary sources rather than to an anatomical structure. Lewis et al. also demonstrated that point A does not maintain a constant relationship to any specific structure and its position varies with the type of applicator, individual tumor anatomy, and age of the patient. No correlation was found between point B and the pelvic wall (90,91). Potish also questions the validity of point A as its position bears no fixed relationship to tumor

or normal tissue anatomy and is in a steep dose gradient and sensitive to displacement (92,93). Point A can be identical for implants that differ in fundamental ways and deliver different overall 3-D dose distributions.

FIGURE 12.29. The definition of point A using the revised Manchester definition becomes problematic when the cervix protrudes between the ovoids, causing an increase in dose rate at point A. Use of the classical Manchester definition of point A (point A defined from the level of the upper vaginal fornices rather than the location of the exocervix) may be helpful.
Source: Reprinted with permission from Batley F, Constable WVC. The use of the Manchester system for treatment of cancer of the uterine cervix with modern afterloading radium applicators. *Am J Roentgenol Rad Ther.* 1967;18:397.

Limitations of Brachytherapy Systems: mg-hr Systems

The use of mg-hr systems also continues at many institutions to guide the choice of source strength and duration of the implant, estimate the risk of complications, compare treatment between patients and institutions, and estimate efficacy (94,95). In the past, little attempt was made to obtain dose information to anatomical structures, and mg-hr prescriptions were not necessarily accompanied by isodose distributions so that the dose prescription was not related to patient anatomy.

Contemporary Dose Specification for Cervical Cancer

The advent of afterloading applicators and computerized dosimetry have brought about a dramatic change in dosimetric analysis (74,96,98). With LDR brachytherapy, the basic principle of 2-D film-based intracavitary prescription is to leave a specific loading of sources in for a definite time, determined by empirical experience, prescription rules, and computerized dosimetry which provides the dose at several anatomic points and isodose distributions (Fig. 12.31). The intracavitary dose is based on the extent of disease and is altered if computer calculations indicated high doses to surrounding critical structures. The rectum and bladder are viewed as tolerance points, compared to point A, which is a treatment dose specification point (97,61). A combination of both mg-hrs and point doses is used at some institutions to guide implant duration (81,101). Though these definitions vary from institution to institution, most will attempt to quantify doses in the paracervical region (point A), and at either point B or the pelvic wall (C or E), and the rectum and bladder (86,87,61). Although intracavitary point dose calculations are not recorded as often for the sigmoid, vaginal mucosa, or cervix, dose evaluation at

FIGURE 12.30. Variations of point A based on definition. A consistent location for dose specification should fall superior to the ovoids where the dose distribution runs parallel to the tandem and not close to bulge of the pear.
Source: Reprinted with permission from Nag S, Chao C, Erickson B, et al. American Brachytherapy Society recommendations for low-dose rate brachytherapy for carcinoma of the cervix. *Int J Radiat Oncol Biol Phys.* 2002;52(1):38.

these points is also helpful. Maruyama et al. defined a point T (tumor dose) located 1 cm above the cervical marker and 1 cm lateral to the tandem, which is usually 2 to 3 times the dose at point A (99) and has been used at other institutions (100,101). Vaginal surface dose rates, defined at the lateral ovoid surface, will vary based on applicator diameter and available source strengths and should be in the range of 1.4 to 2.0 (the point A dose) (83,102).

It has become increasingly obvious that 2-D orthogonal film-based dose distribution analysis, in which single or multiple reference points are chosen on films at the interface of the organs closest to the applicators and at select dose specification points, is inadequate for gynecologic brachytherapy. Single tumor reference points such as Point A, chosen from localization films, do not give sufficient information about the dose distribution throughout the tumor volume. Nor do the reference points for the bladder and rectosigmoid accurately reflect the dose distribution within these organs. Additionally, there is no recognition of the volume of tumor and normal tissues receiving these doses (28). Increasingly, this 2-D approach is now frequently challenged with the advent of MRI and CT compatible applicators and DICOM image transfer used traditionally for external beam plans. Most radiation oncology departments have CT simulators and some are also acquiring MR scanners, making 3-D image-guided brachytherapy a more common reality. Image-based brachytherapy enables defining both the disease and the organs at risk and then shaping the dose distribution to optimally cover disease and exclude the normal tissues (Fig. 12.32). (103,104,28). Directly relating the intracavitary system to the anatomy through use of CT and MRI is the next step in the lineage of dosimetric systems (Fig. 12.60) (28,103–106).

Source: From Perez CA, Grigsby PV, Williamson JF. Clinical applications of brachytherapy. I: Low dose-rate. In: Perez CA, Brady LW, eds. *Principles and Practice of Radiation Oncology*, 3rd ed. Philadelphia, PA: Lippincott-Raven Publishers; 1998:487, with permission.

The American Brachytherapy Society (ABS) has been pivotal in developing guideline for the treatment of gynecologic cancers and these will be cited throughout this text for both LDR and HDR brachytherapy. Initially published by Nag et al. (88,89) these have recently been updated and published (107,61). The HDR guidelines, in particular, emphasize the importance of image guidance in brachytherapy planning.

CT is excellent for delineation of the normal pelvic organs, but is poor in defining tumor in the cervix or vagina. With CT-based computerized dosimetry, rectosigmoid and bladder doses can more accurately be determined than with localization films. Even when using CT compatible applicators, however, the boundaries between structures of interest are poorly defined. The value of MR in the imaging of gynecologic cancers lies in its multiplanar capability and superior soft-tissue resolution, compared to CT, enabling delineation of tumor within the cervix, uterus, and vagina as well as within the parametrial and vaginal tissues (108,109). Tumors of the cervix display moderately increased signal on T2-weighted images relative to normal cervical stroma, permitting definition of tumor volume. This is an advantage during brachytherapy as one can assess the proximity of the tumor to the applicator and the subsequent dose distribution throughout the tumor volume. The excellent soft-tissue resolution of MRI allows visualization of residual tumor in relation to the isodose distribution around the MRI compatible brachytherapy applicators (Figs. 12.33 and 12.60) (108–111). The dose distribution can then be optimally conformed to the defined target volume while accurately defining and limiting the dose to the adjacent normal organs at risk. The Gyn GEC ESTRO working group began to develop guidelines for recording and reporting 3-D image-based treatment planning for cervix cancer brachytherapy in 2000. The guidelines were published in 2005, which described a methodology using MR at the time of brachytherapy to define the GTV and CTV (112,113). The gross tumor volume (GTV) at the time of brachytherapy

was defined as residual tumor following external beam on clinical examination as well as the high signal regions on T2 FSE images in the cervix and paracervical tissues. The high-risk clinical target volume (HRCTV) included the GTV as well as the entire cervix and the extracervical tumor spread at the time of brachytherapy. The “high risk” volume refers to tissues with a major risk of local recurrence because of residual macroscopic disease, which require a high dose of radiation, similar to that delivered traditionally to point A. The Intermediate Risk CTV (IR CTV) was defined as encompassing the high risk CTV with a margin of 5 to 15 mm, and refers to tissues carrying a significant microscopic tumor load. Doses of approximately 60 Gy are intended for this volume. With these different regions of risk defined according to physical examination and MR at the time of brachytherapy, dose volume parameters were defined for the GTV, HR CTV, IR CTV, and the organs at risk (OARS). For the rectum, contouring included the outer wall from the anorectal junction to the rectosigmoid flexure and the sigmoid contour continued alone until the sigmoid was approximately 2 cm from the uterus. The small bowel was contoured only if within 2 cm of the uterus. The outer contours of the bladder were also defined (113,110). D100 and D90, as well as V100, were recommended for reporting as well as the minimum dose in the most irradiated tissue volume for 0.1 cc, 1 cc, and 2 cc of the OARS, contouring the outer walls only (110). The radiobiological model equivalent dose (EQD2) is used to sum the external beam and HDR doses together over the course of treatment so that a cumulative biologically weighted dose is available. This allows for systematic evaluation of the doses to the targets and normal organs over the course of treatment and for comparison between centers.

Additionally, the use of dose-volume histogram analysis may add new insight into optimizing local control and decreasing morbidity with a better understanding of the importance of dose-volume relationships. Data from Potter et al. have shown a decrease in complications and an increase in local control

with the use of MRI-guided brachytherapy for cervical cancer (114,115). The ABS supports these guidelines and has incorporated them into its latest guideline document (107). Though frequently confused, the ICRU 38 system (Dose and Volume Specification for Reporting Intracavitary Therapy in Gynecology) is a dose reporting system, not a dose specification system

(Fig. 12.34) (59). This was developed so that comparisons could be made between centers using different brachytherapy systems. It provides definitions for determining dose to the bladder and rectum in addition to other characteristics of the implant. Updated ICRU guidelines are forthcoming, with an emphasis on 3D planning and dose specification.

Importance of Brachytherapy in Cervical Cancer

When curative treatment is planned, patients with cervical carcinoma treated with definitive irradiation should receive a combination of external beam irradiation and brachytherapy. As revealed in the Patterns of Care Studies (PCS) and the retrospective series of Perez et al., recurrences and complications are decreased when brachytherapy is used in addition to external beam (85,116–119). Use of an intracavitary implant was the single most important treatment factor in multivariate analysis for stage IIIB cervical cancer with respect to survival and pelvic control in the 1973 and 1978 PCS (120,121). Retrospective series with external beam alone have proven marginal outcomes with this approach (122). Common reasons for avoidance of brachytherapy include inability to negotiate the endocervical canal or poor performance status. Inability to negotiate the endocervical canal should be rare with the use of intraoperative ultrasound, and when this occurs, interstitial implantation is a much better option. Even with IMRT and the ability to customize and escalate the dose to specific volumes, brachytherapy cannot be replaced (123–125). The efficacy of brachytherapy is attributable to the ability of radioactive implants to deliver a higher concentrated radiation dose more precisely to tissues than external beam alone, by treating from the “inside out” due to the close proximity of the radioactive source(s) to the tumor, which contributes to improved local control and survival. At the same time, surrounding healthy tissues such as the bladder and rectosigmoid are relatively spared due to the rapid fall-off of dose around the applicators with distance. With IMRT, dose will necessarily be distributed in the surrounding normal tissues as it makes its way to the cervix as the dose is delivered from the “outside in.” The external beam component of treatment is, however, very important as it addresses tissues at a distance from the brachytherapy applicator such as the pelvic lymph nodes. The external beam also brings about tumor regression in intact cervical and vaginal cancers such that the residual tissue is brought within the range of the pear-shaped or cylindrical-shaped radiation dose distribution around standard applicators (58).

Brachytherapy Applicators

Given the importance of brachytherapy, it is important to select the appropriate applicator to accommodate patient anatomy and the disease and shape the associated isodose distribution to encompass the disease. Tumor volume and patient anatomy are key in this decision. Tumor size and shape are variable, and there is a multitude of applicators available to address these diverse presentations.

INTRACAVITARY APPLICATORS: CERVICAL CANCER

Low Dose Rate

There are varieties of LDR applicators available for intracavitary brachytherapy. The best known are the Fletcher-Suit and Henschke tandem and ovoid (colpostat) applicators (Fig. 12.26) (126). In 1953, Fletcher published an article introducing his preloaded radium applicator, which was designed to produce the largest possible volume of adequate radiation in each of the common directions of spread of disease—the uterine body, parametria, and perivaginal tissues—with relative sparing of the bladder trigone and anterior rectum due to the addition of shielding (72,73). The applicator was modified in the 1960s for afterloading (Fletcher-Suit applicator) (79,80,126) and in the 1970s to accommodate ^{137}Cs sources (80). In the 1970s, the Delclos mini-ovoid was developed for use in narrow vaginal vaults (Fig. 12.26) (79,127). The mini-colpostats have a diameter of 1.6 cm and a flat inner surface. The mini-ovoids do not have shielding added inside the colpostat, and this together with their smaller diameter produces a higher surface dose than

FIGURE 12.34. Reference points for bladder and rectal brachytherapy doses proposed by ICRU.

regular ovoids with resultant higher doses to the rectum and bladder. Appropriate source strength and treatment duration adjustment are important considerations to prevent complications. Fletcher tandems are available in 4 curvatures, with the greatest curvature used in cavities measuring >6 cm and lesser curvatures used for smaller cavities (Fig. 12.26). A flange with keel is added to the tandem once the uterine canal is sounded, which approximates the exocervix and defines the length of source train needed. The keel prevents rotation of the tandem after packing. The distal end of the tandem near the cap is marked so that rotation of the tandem after insertion can be assessed. PDR adapted applicators are also now available but are much more like HDR applicators than their LDR equivalents (60,61).

The Henschke tandem and ovoid applicator was initially unshielded (126,128) but later modified with rectal and bladder shielding (100,101,61). It consists of hemispheroidal ovoids with the ovoids and tandem fixed together. Sources in the ovoids are parallel to the sources in the uterine tandem (100). The Henschke applicator may be easier to insert into shallow vaginal fornices in comparison to Fletcher ovoids.

The Fletcher-Suit-Delclos tandem and cylinder applicator was designed to accommodate narrow vaginas where ovoids may be contraindicated and to treat varying lengths of the vagina when mandated by vaginal spread of disease. The cylinders vary in size from 2 to 5 cm to accommodate varying vaginal sizes (Fig. 12.26) (127). A narrow vagina poses a therapeutic challenge. Use of vaginal cylinders may lead to a higher rate of local failure as the dose to the lateral cervix and pelvic sidewall is reduced in the absence of ovoids, which produce the optimum pear-shaped distribution. These patients also tend to receive lower total doses due to the proximity of the rectum and bladder (Fig. 12.35) (84). There is less of a dose gradient between the vaginal mucosa and the bladder and rectum than in a patient with a wider vagina (129). Additionally, packing cannot be used with cylinders to decrease the rectal and bladder doses (130–133). Vaginal cylinders increase the length of vagina and rectum treated, with an associated increase in complications. Vaginal fistulae, rectal ulcers, and strictures are reported with increased frequency when vaginal cylinders are used (134–136). Pourquier et al. indicated that doses should be reduced with the use of vaginal cylinders and mini-ovoids to reduce complications as these applicators have no shielding (137,138). Interstitial implantation should also be a

consideration for patients with a narrow vagina or with distal vaginal disease.

The Importance of Optimal Applicator Placement

Geometrically optimal intracavitary implants improve outcome over suboptimal implants. Corn et al. reported an analysis of the 1978 and 1983 PCSs, which attempted to analyze the outcome of cervical cancer patients by the technical quality of the implant. A technically good implant correlated significantly with improved local control, with a trend toward improved survival (139). In a review of the RTOG 0116 and 0128 trials, the quality of applicator placement was statistically related to the risk of local recurrence and disease-free survival (140). Perez et al. observed that “inadequate” insertions increased the incidence of pelvic failures (116) and that the quality of the intracavitary insertion had a measurable impact on the incidence of complications (141). Attention to the details of implant geometry has been linked to improved outcome in the series of Katz and Eifel at M.D. Anderson (83). Prior to afterloading, it was much more difficult to obtain adequate applicator placement due to the need to complete the insertion quickly to avoid excessive exposure to the sources in the preloaded applicators. In the era of afterloading, applicator placement can be more methodical. Orthogonal films or other imaging (CT, magnetic resonance imaging [MRI]) should always be obtained following applicator placement to assess applicator geometry and the need for adjustment to ensure optimum placement. It is imperative that geometrically favorable applicator placement, as described in detail previously by Fletcher, be achieved in as many patients as possible.

Optimum applicator placement is pivotal in maximizing local control. Placement of the brachytherapy applicators in direct proximity to the cervix is necessary to avoid underdosage. There will be a cold spot if the ovoids or other vaginal applicators are displaced away from the cervix (Fig. 12.36). Proper applicator selection is important in avoiding malpositioning. It is extremely important to place metallic markers on the cervix so that the flange of the tandem and the ovoids/cylinder dome are positioned in close proximity to these markers as confirmed on orthogonal check films (83,61).

Likewise, suboptimal applicator placement can increase the risk of complications. Applicators that are too close to the

FIGURE 12.35. MRI/CT compatible tandem and cylinder applicator with associated isodose distribution in **A:** axial and **B:** sagittal views, demonstrating the close proximity to the rectum due to the absence of packing or rectal retraction.

FIGURE 12.36. Lateral radiograph of a poorly positioned HDR tandem and ovoid applicator. Note that the tandem does not bisect the ovoids and that the ovoid appears to be displaced inferiorly from the cervical marker balls.

bladder and rectum can increase rectal and bladder complications. Sources in the tandem can give very high doses of radiation to the small bowel (ileum), sigmoid, and upper bladder, often not revealed by orthogonal X-rays. Tandems that have perforated through the uterus can cause tremendous hot spots in the nearby normal organs (82).

Interstitial Applicators: Cervical and Vaginal Cancers—LDR and HDR

The size of the reference pear-shaped isodose achieved with tandem and ovoids is not variable except by increasing the duration (dose) of the implant. The shape of the reference pear-shaped isodose can be altered to some degree by varying the source strengths and applicator type, but it may not be able to encompass a bulky tumor, particularly when there is bulky parametrial or vaginal disease. In these settings, the disease may be better accommodated by an interstitial application (Fig. 12.37) (142). Patients with large, bulky lesions will have a higher rate of local failure because of a decrease in dose to the periphery of the tumor due to the rapid fall-off of dose beyond the relevant pear-shaped distribution. The use of higher doses of external beam prior to implantation and interstitial techniques are important considerations. These patients should not be treated with external beam alone, as achieving the curative radiation doses required may be impossible because of the limited tolerance of the interposed small bowel, rectum, and bladder. Standard intracavitary applications may be suboptimal or prohibited either by tumor bulk or by distorted normal anatomy, and these patients should not be treated with geometrically unfavorable intracavitary implants.

Indications for Transperineal Interstitial Implantation of Gynecologic Malignancies

1. Bulky Disease
 - IB Barrel
 - IIB, III, IVA
2. Anatomical Distortion
 - Narrow/obliterated vagina
 - Obliterated fornices
 - Stenotic/obliterated endocervical canal
3. Recurrent Disease

FIGURE 12.37. Indications for interstitial implantation and associated AP radiograph of the implanted needles.

The limitations of intracavitary techniques contrast with the strengths of interstitial techniques in certain settings. Determine which approach is best on a patient-by-patient basis. Interstitial implantation is appropriate in select patients with bulky tumors, anatomical distortion such as an obliterated endocervical canal or narrow vagina, or recurrent disease (142). Interstitial implantation is used in <10% of patients with gynecologic cancers (143). Attention to patient comfort during and after the procedure, integration of appropriate imaging for ideal needle insertion relative to the tumor and dose specification/fractionation, and minimization of both acute and late morbidity are key in achieving a successful outcome. Typically these are performed in higher volume centers through the combined efforts of *Radiation Oncology* and *Gynecologic Oncology* (144). The ABS has recently published consensus guidelines for LDR and HDR interstitial brachytherapy for cervical and vaginal cancers summarizing the most current recommendations (61,145).

The development of prefabricated perineal templates, through which stainless steel needles were inserted and after-loaded with ^{192}Ir or ^{125}I , was pivotal in advancing interstitial techniques for the treatment of cervical and vaginal cancers. With these interstitial techniques, rather than doing a freehand implant, the template concept allows for a predictable distribution of needles inserted across the entire perineum through a perforated template according to an optimum pattern. Commercially available and institution-specific templates are used in these patients to accommodate varying disease presentations. Stainless steel and plastic needles are used, which are after loaded with low- or high-activity ^{192}Ir sources. The MUPIT (Martinez Universal Perineal Interstitial Template, Beaumont Hospital, Royal Oak, Michigan, USA) template (Fig. 12.38) accommodates implantation of multiple pelvic-perineal malignancies (prostate, anorectal, gynecologic) (142,146,147). In this system, one template accommodates many different disease presentations. Recent modifications of this template and needle system enabling HDR implants have become available (148). The Syed-Neblett (Best Industries, Springfield, Virginia, USA) is the other well-known commercially available template system (142,149,150). Currently, there are three LDR Syed-Neblett templates of varying size and shape for use in implantation of gynecologic malignancies (GYN 1-36 needles, GYN 2-44 needles, GYN 3-53 needles), as well as templates for implantation of the anus, prostate, and urethra (142) (Fig. 12.39). There is also a disposable template for gynecologic presentations that accommodates HDR needles (151–153).

Combination of external beam irradiation and multiple-site perineal applicator (MUPIT) for treatment of locally advanced or recurrent prostatic, anorectal, and gynecologic malignancies. *Int J Radiat Oncol Biol Phys.* 1985;11:391–398, with permission from Elsevier.

The Syed-Neblett and MUPIT templates are particularly suited for treatment of vaginal disease as the vaginal obturator needles can be strategically loaded to encompass disease from the fornices to the introitus. Additionally, the obturator needles can be advanced directly into the cervix, along with a uterine tandem, and may be essential to deliver tumorcidal radiation doses to the cervix by preventing a central “cold spot,” especially if an intrauterine tandem is not used (142,144,145). Use of an intrauterine tandem along with interstitial needles has been statistically associated with an improvement in overall survival in stage IIIB cervical cancer (154). The more peripheral needles are used for implantation of the parametria, which is often underdosed in intracavitary approaches. Modifications of these standard templates have evolved and other innovative templates have been developed for vulvar, vaginal, and cervical

carcinomas (142). Attention to the depth of needle insertion as well as to the number and location of needles is key in achieving an optimum implant (142,149). Additionally, modification of the ring and ovoid applicators to accommodate a limited number of needles to improve tumor coverage has been reported recently, with improved local control in patients with bulky IIB and IIB disease (115,155–157). In these applications, only 10–20% of the dwell time is contributed from source positions in the needles and the remainder by the intracavitary component of the applicator (107). Individualized computer-generated dosimetry is an integral part of interstitial dose delivery. CT imaging following needle implantation has proven very helpful to identify tumor volume and critical normal structures, confirm the adequacy of needle placement in relation to these structures or needed adjustments, analyze and manipulate the

dose distribution related to these structures, and assist with dose specification and the integration of external beam irradiation (142,158). Postprocedure epidural anesthesia provides optimal pain control and allows the needles and tandem to be manipulated outside the operating room if necessary. Modification of the planned source placement based upon the location of specific needles and critical structures can therefore be made before or after source loading (144).

With LDR techniques, traditional LDRs are the goal (142,61), achieved through differential loading (core sources $\leq 1/2$ activity of peripheral sources) of low-activity sources. “Reference” dose rates, of 60 to 80 cGy/hr are optimal. The implant dose rates as well as the dose homogeneity and distribution, can be manipulated by selectively changing the activity associated with a particular needle or needles or by selectively unloading, either immediately or during the implant, strategic needles in the pattern. With HDR techniques, optimization of the dose distribution with predetermined parameters for the reference dose, normal organ doses, and dose homogeneity can produce even more ideal implant dosimetry (Fig. 12.40). Typically, total LDR doses to the tumor volume or reference isodose from the implant range from 23 to 40 Gy over 2 to 4 days for a total dose of 70 to 80 Gy (158,61,142). The total HDR dose will be approximately 60% of the total LDR dose and will be given in divided fractions. There is not a consistent data relative to EQD2 doses when using 3-D image-based HDR interstitial brachytherapy techniques. These seems to be a consensus that the doses are lower than with combined intracavitary HDR and external beam, perhaps on the order of an EQD2 of 75 to 80 Gy (107). With either approach, careful attention to significant hot spots within the implant and doses to the bladder, rectosigmoid, and vaginal surface are requisite to obtaining the best outcome (145,153,142,144).

External whole pelvic irradiation (39.6 to 45.0 Gy) generally precedes implantation. For either LDR or HDR, one or two template implants can be done 1 to 2 weeks following external beam. With HDR, 1 to 2 fractions can be delivered per day over a period of 2 to 5 days, whereas with LDR, continuous hourly

FIGURE 12.40. Axial CT scan with needles inserted into the cervical and paracervical tissues between the bladder and rectum. Isodose curves shown are 80%, 100%, and 120% of the prescription dose.

radiation is delivered. After the implant, selective external irradiation boosting can be done as needed. The total LDR dose to the reference volume from the combined implant and external beam approximates 70 to 85 Gy over 8 weeks (144).

HDR Brachytherapy for Cervical Cancer

Though LDR techniques have been the traditional standard for decades for gynecologic brachytherapy, there appear to be some inherent advantages with the implementation of HDR techniques (159–161). Because the treatment time is very short, treatment is performed on an outpatient basis without the need for several days of bed rest, with greater patient acceptance and comfort. This allows treatment of some patients with medical comorbidities, which would prohibit LDR techniques because of the prolonged bed rest. With the shorter treatment time, the implant reproducibility is superior to traditional LDR approaches as more stable positioning of applicators is possible. The shortened treatment time provides a greater degree of certainty that the sources will remain in the 3D positions documented in the isodose distributions, and that applicator displacement as a function of time will be decreased. The use of external applicator fixation devices allows more constant and reproducible geometry of source positioning (161–163). The newer systems, which allow a single source to “dwell” at a site for a calculated period of time, combined with dose optimization software programs, provide a significant further improvement in the ability to shape the dose distribution. The small source size allows for finer increments in source location and relative weighting for each source location than with the fixed source sizes and activities inherent to the LDR ^{137}Cs sources (89,163,164). This allows for greater precision coupled with greater flexibility and perhaps a reduction in normal tissues doses. Additionally, the rectal retraction devices available with the HDR applicators maximize displacement of the rectum for short periods of time and may give superior and more predictable displacement than traditional vaginal gauze packing (161–163). These 2 factors lead to improved dose

delivery to the tumor relative to surrounding normal tissues. There is also increased integration of external beam with HDR, as external beam irradiation can be given 3 to 4 times per week and HDR 1 to 2 times per week. This can lead to shorter overall treatment duration, which may be pivotal in maximizing cure (165,160). Additionally, due to the small physical size of the ^{192}Ir source, the HDR applicators are lighter and smaller than bulky LDR applicators and are easier to insert, particularly if there is vaginal narrowing. Many institutions use only 1 LDR implant so that if the applicator geometry is poor, there is not the opportunity to perform multiple implants and improve the geometry or change applicators in future insertions as realized with HDR techniques. The remote afterloading also provides a lack of radiation exposure to healthcare providers. Contrastingly, on a radiobiologic basis, HDR lowers the therapeutic ratio compared to LDR, as there may be more late effects of radiation if the rectosigmoid and bladder receive as much radiation as the tumor than with LDR techniques. For HDR to succeed, the geometric advantages must overcome the radiobiologic disadvantages (163). Himmelmann et al. concluded that with HDR regimens, reoxygenation of hypoxic cells can take place between fractions, and this may in fact be a radiobiologic advantage of HDR (166). Disadvantages of HDR may include loss of the radiobiologic advantage of LDR, decreased time for normal tissue repair, a potential increase in late tissue effects with large fraction sizes, and an increase in the number of implants per patient from 1–3 to 3–6 (range, 2–16), which is labor intensive for all involved (160). The need for sedation may still exclude high-risk patients even though bed rest is not required.

Conversion from LDR to HDR

There have been numerous suggestions regarding how to convert total LDR doses to HDR doses in order to implement reasonable dose-fractionation schemes. Efforts have been made by many investigators to compare the biologic effects of LDR with HDR regimens using various dose conversion models. The linear-quadratic model has typically been used, but this does not address the optimal number of fractions. A basic concept is that the total dose with HDR must be less than with LDR and the number of fractions must increase (166–168). This concept comes from early radiobiologic studies. The Equivalent Radiation Dose (ERD) mathematical model can be used to determine the HDR dose per fraction (169,170). The ERD is a biologic dose unit, which utilizes the linear-quadratic model. To determine an appropriate dose for HDR treatments based upon LDR techniques, the ERDs are assumed to be equal. The α/β for tumor is assumed to be 10, while μ is assumed to be 1.4 hr^{-1} . For this calculation, the LDR total dose, LDR dose rate, and desired number of HDR fractions are required to calculate an HDR fraction size. These calculations have shown that one must give approximately 60% to 70% of the LDR dose with HDR. The conversion of doses herein is strictly for the brachytherapy component of the treatment course (159,169,170). More recently, there has been interest in calculating the equivalent dose (EQD2) at 2 Gy per fraction for both the radiation targets (Point A, HR CTV) and the OAR (organs at risk) when adding together both the external beam and the brachytherapy components of treatment. This can be done for LDR, PDR, and HDR. This interactive worksheet is available through the American Brachytherapy website (107).

HDR Applicators

The tandems and ovoids used with HDR are variations of the traditional Fletcher and Henschke LDR applicators but are lighter, narrower, and smaller (Fig. 12.41) (107). The ovoids are 2.0, 2.5, and 3.0 cm in diameter with and without shielding. The

FIGURE 12.41. HDR tandem and ovoids.

Source: Courtesy of Nucletron.

relationship of the colpostat to the handle is different between HDR and LDR colpostats so that the cable-driven HDR source can negotiate the angle between the handle and the colpostat. The Selectron colpostats are angled at 60° to the applicator handles. Standard Fletcher-Suit LDR colpostats are angled most often at 15° and sometimes at 30° with respect to the colpostat handles (Fig. 12.42). This can lead to a different relationship between the tandem and the colpostats and between the colpostats and the cervix, best seen on the lateral orthogonal X-rays taken for dosimetry after applicator insertion. As previously mentioned, these applicators have also been adapted for needle insertion for bulkier tumors (155,156).

The ring applicator, which is an adaptation of the Stockholm technique, has become a popular applicator (164,171–174) (Fig. 12.43). The plastic caps that come with the ring applicator place the vaginal mucosa 0.6 cm from the source path, compared to the caps for the ovoids, which distance the vaginal mucosa from the source path by 1 to 1.5 cm. The short distance from the ring to vaginal mucosa can result in very high surface doses if fixed weighting, nonoptimized techniques are used (161,173). The bladder and rectum may also receive higher doses with fixed weighting nonoptimized dosimetry (172). It is important not to activate all the positions in the ring, as this will increase the dose to the rectum, bladder, and vaginal mucosa (172). Typically, four dwells are activated on each side of the smallest ring (36 mm), five on each side of the medium ring (40 mm), and six on each side of the large ring (44 mm). The tandems are available in lengths of 2 to 8 cm. Four ring-tandem angles are available including 30° , 45° , 60° , and 90° . The shape of the isodose curves comparing the ring with tandem and ovoids will also have a different shape and the volume of tissue irradiated will also differ (172,173). The ring applicator is ideal for patients without lateral vaginal fornices. Its ease of insertion and predictable geometry make it a popular alternative to tandem and ovoids. As previously mentioned, the ring applicator has also been adapted to accommodate needles for patients with bulky tumors (115,157).

Tandem and cylinder applicators are used in the setting of a narrow vagina or vaginal extension of disease and are available in diameters of 2.0 to 4.0 cm (Fig. 12.44). In most cases, rectal and bladder displacement are not possible with this applicator, although some of the cylinders have built-in shielding. A posterior speculum blade to displace the rectum can be used if there is not posterior vaginal disease. As with LDR tandem and cylinder applicators, the bladder and rectal doses may increase with this

FIGURE 12.42. LDR versus HDR ovoid angles. The low dose rate ovoids are positioned at a 15° or 30° angle to the vaginal axis versus 60° in the HDR ovoids.

Source: Courtesy of Nucletron.

applicator, and the dose distribution will be more cylindrical than pear-shaped, which can underdose bulky tumors (Fig. 12.35). Careful attention to normal tissue doses and target coverage is necessary in this setting (107).

HDR Treatment Planning

The dose distribution with HDR tandem and ovoids and tandem and ring applicators model the LDR pear-shaped isodose distribution. Most HDR regimens use a paracervical dose specification point (A) rather than mg-hrs or a volume-based dose specification such as the HR CTV (107). Rectal, bladder, sigmoid, and vaginal surface doses should always be specified or

FIGURE 12.44. Tandem and cylinder applicator.

documented, and some assessment of dose to the pelvic lymph nodes and lateral parametria should be documented.

The HDR system utilizes special vocabulary to describe certain functions and applications. A “dwell position” is a position at which the source is driven to stop or dwell. Dwell positions can be 2.5 and 5 mm apart. An active length will be converted into a number of dwell positions. “Patient points” are points of interest at which the dose is calculated; they are defined on the orthogonal implant films. Examples include bladder, rectum, and sigmoid. “Applicator points” are points of interest at which the dose is calculated; they are defined by manually inputting the coordinates. Typically, applicator points include point A and points on the lateral surface of a ring, ovoid, or cylinder. “Dose points” are points at which the dose is optimized. In general, doses are specified using dose points. The optimization program then attempts to give the prescription dose at each of these points. With the tandem and ring, a similar system is used. The entire ring should never be activated, as this will cause high rectal, bladder, and vaginal doses. For the tandem and cylinder, again, a similar system is used with the exception that at the cylinder interface, dose points are entered laterally from the dwell positions at the distances representing the cylinder surface. Due to the close proximity of the bladder and rectum in women requiring vaginal cylinders because of a narrow vagina, dose specification needs to be done with great care so as not to give excessive doses to the bladder and rectum. Dose specification at point A alone can result in underdosing of target tissue and overdosing of dose-limiting tissues (175–177). If using 2-D planning, in addition to point A, specifying dose at the

FIGURE 12.43. Tandem and ring applicator with associated rectal retractor.

Source: Courtesy of Nucletron.

vaginal applicator surface is important. If using a volume-based approach, dose specification to the HR CTV while negotiating the doses to 2 cc of the bladder and rectosigmoid is key. With either approach optimization of the dose distribution follows and enables design of a more ideal dose distribution (Fig. 12.45). The term “optimization” refers to the process of achieving certain dose values at points or volumes within the implant. It is not the simple generation of a standard dose distribution by using fixed dose points around the applicator (107). The goal is to match the dose distribution to point A or the HR CTV while simultaneously avoiding the OAR. Inherent to optimization is starting with a standard plan of loading the tandem and the vaginal applicator and then modifying the dwell times and dwell weights to reduce dose to the OAR and ensure optimal tumor coverage (107). Excessive optimization can alter the pear shape to a less desirable configuration with the same point A dose (176,177). When altering the standard dwell times and weights, it is important to also monitor changes in the dose, dose/volume parameters and the spatial dose distribution that result from the modified loading pattern. Reliance on dose volume histograms alone can be dangerous if not also evaluating the spatial dose distribution (107). The entire length of the tandem does not always need to be treated and should be guided by the definition of remaining tumor at the time of brachytherapy seen on MR or CT. This can reduce dose to the OARs (178). Likewise, activation of dwell positions in the vaginal applicator should also be considered carefully in light of the closely approximated bladder and rectum and vaginal target.

HDR Dosimetry Generation

It is important to perform dosimetry for each fraction of an HDR tandem and vaginal applicator regimen even if the same applicator is used, as there may be quite a bit of variation in applicator position with each fraction (179–187,107). There is also applicator deformation of the adjacent structures, which varies with applicator position (182). Variables that impact applicator position are vaginal packing, the presence and effectiveness of sedation/anesthesia, as well as use of the dorsal lithotomic versus legs down position. The bladder and rectosigmoid may also change configuration due to changes in filling and position, and doses to these organs will vary from fraction to fraction. Uterine and sigmoid mobility may also impact the dose distribution in

these organs. Additionally, disease regression and vaginal narrowing will vary from fraction to fraction and can also result in changes in dose distribution. A change in applicator can also result in changes in dose distribution, as can changing the ovoid or ring size, ovoid separation, and tandem curvature. The ovoids may also change in separation and their relative position to the tandem over time if there is not a fixed relationship between the tandem and ovoids (181,183–186). Jones et al. found that when treatment planning was not performed for each fraction and only the initial dosimetry was used, there was increased dose to at-risk normal organs (186). This is also true when using a tandem and ring, even though it has a fixed geometry. The applicator position relative to the pelvic organs is the important factor rather than the relationship of the tandem to the ring (Fig. 12.46).

Dose-Fractionation Schemes

In the 1990 literature review by Fu and Phillips of the randomized and nonrandomized studies of HDR, multiple dose-fractionation schemes were tabulated. Most centers used point A as a reference point, although the definition of point A varied. The dose per fraction at point A varied from 3 to 10.5 Gy, the number of fractions varied from 2 to 13, and the number of fractions per week varied from 1 to 3. At that time, most centers used a schedule of 7 to 8 Gy/fx for three to six fractions. The external beam dose was variable and in most centers was carried out concurrently with or after intracavitary brachytherapy (188). The 1991 Orton et al. survey of 56 institutions reported treatment of over 17,000 cervix patients with HDR and found that the average fractionation scheme was 5 fractions of 7.5 Gy to point A. Fractionation of the HDR treatments significantly influenced toxicity as morbidity rates were significantly lower for point A doses per fraction of ≤ 7 Gy compared with >7 Gy (189,190). Fraction sizes <7.5 Gy were subsequently recommended by the ABS in one of its earlier guideline documents (89). In a literature analysis by Petereit and Pearcey of the HDR fractionation schedules, a dose–response relationship could not be identified for tumor control or complications (191). There is no consensus as to the optimal number of fractions and dose per fraction except that the choice will depend on the external beam dose and on whether central shielding is used, normal tissue doses, medical comorbidities, and the stage of disease. The linear-quadratic model was suggested as a guide to formulate the regimens chosen at each institution (89,192). Currently, Gynecologic Oncology Group (GOG) protocols define a dose/fractionation scheme of 5.6–6.3 Gy $\times$ 5 to point A with whole pelvis doses of 41.4–45 Gy. Radiation Therapy Oncology Group (RTOG) protocols allow fraction sizes of 5.3 to 7.4 Gy when using 4 to 7 fractions, depending on the external beam dose. Tables for combining various external beam doses with varying HDR fractions using the linear-quadratic formula and normal-tissue-modifying factor have been provided with these protocols (192). There has been increasing concern that 6 Gy times 5 to point A may result in excessive toxicity to the rectum and sigmoid when combined with whole pelvis doses of 45 Gy and a dose of 5.5 Gy times 5 to point A may be more reasonable (193,107). In the United States, the most common HDR intracavitary regimen prescribes 2 fractions per week for a total of five fractions, with 5–6 Gy per fraction (194). Internationally the most common dose per fraction was between 5–7 Gy with the higher dose per fraction associated with a decrease in fraction number (3–5 fractions) (143). When using volumetric image-guided brachytherapy, the dose at Point A can still be tracked but the goal is to guide coverage of the HR CTV with acceptable OAR doses for an EQD2 of 80–90 Gy, depending on the volume of disease remaining at the time of brachytherapy. The EQD2 limit to the D2cc (the minimum dose in the most irradiated 2 cm³ normal tissue volume for the rectum and sigmoid is 70–75 Gy and for the bladder, 90 Gy (107).

Sequencing with External Beam

In nonbulky disease presentations, HDR insertions are often integrated early in the treatment course after approximately 20 Gy of external beam RT. Alternatively, some institutions choose to take the whole pelvis to 40 to 45 Gy initially, preceding the five HDR insertions, unless the patient has very early disease or evidence of early vaginal stenosis. This allows for maximum disease regression prior to brachytherapy. When delivering 40 to 45 Gy to the whole pelvis before initiation of HDR, it is important to avoid treatment prolongation by giving two HDR fractions per week to complete the radiation within 50 to 56 days (107). Compressing the duration of treatment to <60 days may be desirable (165,194–196).

Brachytherapy for Endometrial Cancer

Hysterectomy is the cornerstone of treatment for endometrial carcinoma. Selective use of vaginal brachytherapy, external beam irradiation, or both in the postoperative setting is based on the histopathologic risk factors identified in the tissues removed at the time of surgical staging. Vaginal brachytherapy is typically performed using Fletcher colpostats, or a variety of vaginal cylinders (Delclos, Burnett). Both LDR and HDR techniques are used (197,198,199) (Fig. 12.48). The choice of ovoids versus cylinders is individual and both have relative advantages and disadvantages (194). Vaginal ovoids are available in diameters of 2 to 3 cm with associated caps and shielding. Vaginal cylinders are available in diameters of 2 to 5 cm, with or without shielding. Vaginal ovoids generally require sedation for insertion, whereas cylinders do not. The length of the vagina treated with vaginal ovoids is approximately the upper third, whereas vaginal cylinders can treat a portion of or the entire vagina. Though rare, when present, distal vaginal metastases tend to be located in the periurethral area (200,201). Poorly differentiated tumors may

recur earlier and present in the distal vagina or distant disease sites, whereas well-differentiated lesions tend to recur later and are often in the upper vagina (202). Distal vaginal recurrences or metastases, however, are rare after radiation and occurred in 0.5% to 1% of patients when the upper vagina was treated (203). It is therefore not suggested to treat more than the upper half of the vagina routinely. Typically, the length of vagina treated with vaginal cylinders is between 4 and 5 cm, perhaps favoring a longer length when using brachytherapy alone (197,198). Packing is typically used to displace the rectum and bladder with ovoids and not with cylinders. Due to the longer length of vagina treated and the lack of packing, a larger volume of rectum and bladder will be treated with cylinders. Vaginal ovoids may be prohibited in a narrow vagina, whereas vaginal cylinders may not be in close approximation with all of the vaginal mucosa in the setting of a wide vaginal apex or if the cuff has been closed with “dog ears” rather than in a cylindrical shape.

Most vaginal brachytherapy for endometrial cancer is performed with vaginal cylinders using HDR techniques (Fig. 12.48) (197,198). The dose distribution should ideally conform to the shape of the cylinder (204,198). Dose is typically specified either at the vaginal applicator surface (mucosal surface) or at a depth of 0.5 cm from the applicator or vaginal mucosal surface. Dose prescription at 0.5 cm can lead to excessively high mucosal doses and surface doses should also be tracked (205,206,198). Additionally, careful assessment of dose to the rectum and bladder through use of computerized dosimetry should also be performed for the first fraction of radiation delivered (Fig. 12.48). CT-based planning allows for an excellent assessment of the doses to the bladder and rectum as well as evaluation of air gaps at the interface of the applicator surface and vaginal mucosa, but is only needed for the first fraction (Fig. 12.48) (207,208,198). Choo et al. have revealed that 95% of the vaginal lymphatic channels are located within 3 mm of the vaginal surface and that dose prescription to a depth of less than 5 mm may be adequate (209). For LDR insertions, dose

FIGURE 12.47. Midline blocks: A midline block defined by the leaves of the multileaf collimator used to shield the central pelvic structures. Note the unblocked bladder and sigmoid that may get some of the brachytherapy dose and all of the external beam dose.

rates at the surface of the applicator should be in the range of 80 to 100 cGy/hr, and perhaps 50 to 70 cGy/hr if the prescription is at 0.5 cm (204). Total vaginal surface doses of 50 to 80 Gy are reported most frequently in the literature. When used with external beam, cumulative doses of 60 to 100 Gy at the vaginal surface are reported in the literature. Doses in excess of 80 Gy to the vaginal mucosa are not necessary in the setting of adjuvant therapy and can be associated with increased morbidity. For a vaginal recurrence of endometrial cancer, doses of 80 Gy and higher may be needed when combining external beam and brachytherapy (210).

Vaginal brachytherapy alone is generally considered an option for patients treated with hysterectomy, with either no or selective lymph node sampling, who are thought to be at low risk for lymph node metastases. These patients typically have grade 1 or 2 disease without significant myometrial invasion (<1/3) (211,212,198). Additionally, vaginal brachytherapy alone is considered an option at some institutions in the setting of a negative pelvic lymph node dissection, even when high-risk factors such as high grade or deep myometrial invasion are present (212–214,198).

There is great debate about whether a vaginal cuff boost is routinely necessary in addition to external beam irradiation for early-stage endometrial cancer and little data to support it (215,216,198). Practice patterns are based more on institutional tradition and individual preference rather than prospective randomized trials. The rationale for use of a vaginal boost is the supposition that there may be a critical dose needed at the vaginal apex to optimally decrease the likelihood of a vaginal apex recurrence. Doses in excess of the 45 to 50 Gy typically delivered with external beam may be necessary if there are microscopic tumor cells embedded in the hypoxic vaginal cuff.

There are some clinical situations in which more complex brachytherapy procedures are required in the treatment of endometrial cancer. Patients with bulky stage II endometrial cancers may benefit from preoperative radiation with external beam alone, brachytherapy alone, or a combination of the two. Tandem and ovoids or tandem and ring or cylinder applicators are used in this setting. Medically inoperable endometrial cancer is a rare phenomenon in the current era of aggressive surgical staging.

When encountered, it can require the use of sophisticated radiation techniques. Either external beam alone or brachytherapy alone or a combination of the two may be appropriate for some patients. Tandem and ovoids or a tandem and ring or cylinder may be appropriate if the uterine cavity is small. If the uterus is large or if there is more extensive disease, special uterine applicators such as dual and triple tandems or Heyman-Simons capsules may be helpful (Fig. 12.49). There is better coverage of the entire endometrial cavity with these applicators, and dose can be delivered through the uterine wall to the serosa of the uterus (217–219). HDR and LDR techniques can be used.

Patients with recurrent endometrial cancer usually benefit from both external beam and brachytherapy. Doses in excess of 80 Gy may lead to better local control in these patients (210). In patients with residual vaginal disease less than 0.5 cm in maximum thickness, vaginal cylinders or ovoids can be used, whereas in patients with thicker lesions following external beam, interstitial techniques are needed. For apical lesions, laparotomy or laparoscopy may be required for optimum needle placement and to avoid small bowel tethered to the pelvic floor (142,220–222).

EXTERNAL BEAM IRRADIATION FOR GYNECOLOGIC CANCERS

Cervical and Vaginal Cancers

In cervical and vaginal cancers, the role of external beam irradiation is to shrink bulky tumor prior to implantation to bring it within range of the high-dose portion of the intracavitary dose distribution, improve tumor geometry by shrinking tumor that may distort anatomy and prevent optimal brachytherapy, and sterilize paracentral and nodal disease that lies beyond reach of the intracavitary system (77). Some institutions maximize the brachytherapy component of the treatment regimen and perform the first intracavitary insertion after 10 to 20 Gy with subsequent external beam delivered with a central block (222). Other institutions treat the whole pelvis to 40 to 50 Gy and perform brachytherapy once the external beam is completed. The total dose at point A or the HR CTV, however, should remain the same, stage for stage. Implementing brachytherapy early with subsequent reliance on only the implant to treat the central disease may be considered an advantage as a greater portion of the central dose is delivered with the implant, with relative sparing of the bladder and rectum, perhaps permitting delivery of a higher central dose over a shorter period of time (223). More reliance, however, is placed on the extremely complex match between the intracavitary

system and the edge of the midline block, making good implant geometry imperative when brachytherapy contributes a large portion of the central dose. Those who prefer to deliver an initial 40 to 45 Gy of external beam first believe that the ability to deliver a homogeneous distribution to the entire region at risk for microscopic disease and the ability to have more shrinkage of central disease prior to intracavitary irradiation outweigh other considerations. The brachytherapy dose is accordingly decreased to respect normal tissue tolerance. In addition to causing regression of central disease, the external beam fields are also directed at the regional lymph nodes at risk. In cervical and vaginal cancer, the risk of pelvic lymph node involvement is related to the stage of disease, tumor size, and lymphatic vascular space invasion. Other histomorphologic factors influencing lymph node involvement in cervical cancer include pathologic tumor diameter, depth of stromal invasion, uterine body involvement, parametrial spread, and the number of cervical quadrants involved by tumor (224). Early necropsy studies reported the lymphatic pathways for patients with cervical cancer (225). The primary lymphatic pathway is to the parametrial and paracervical nodes, and the obturator and internal and external iliac nodes. Secondary spread can occur to the sacral and common iliac nodes, with subsequent spread to the paraaortic nodes. Unlike in endometrial cancer, paraaortic lymph node involvement in the absence of pelvic lymph node involvement is rare. Inguinal lymph node involvement occurs with distal vaginal spread of disease or via the round ligament if there is extensive involvement of the corpus. The cervical lymphatics are located in 3 plexuses in the mucosa, muscularis, and serosa of the cervix and anastomose extensively with the lymphatics of the uterine isthmus. This interconnected lymphatic supply is one of the reasons why the entire uterus should be within the external beam fields when treating cervical cancer. Additionally, there may also be lower uterine segment and endometrial extension of tumor. There are lymph vessels running posteriorly in the uterosacral ligaments to lymph nodes located in the sacrum between the rectum and internal iliac vessels. These posterior nodes may terminate in the common iliac, subaortic, or paraaortic lymph nodes (224,226,227). Recent CT studies have added further information on the location of these lymph nodes and variants of spread (228).

For all gynecologic cancers, these patterns of lymphatic spread influence the external beam field borders. Traditionally, design of “standard” pelvic fields, as shown in many radiation oncology textbooks, has been thought to be quite simple and straightforward and based primarily on skeletal landmarks. The skeletal landmarks are not sufficient for field design (229–231). Traditionally, many institutions have used the “four-field box” technique to treat the pelvis with typical AP–PA field sizes of 15 × 15 cm and lateral field widths of 8 to 9 cm (Fig. 12.50) (82). The intent of the 4 fields is to use rather narrow lateral beams to avoid some of the small bowel anteriorly and a portion of the rectum posteriorly. As radiation technique must be “predicated on knowing where things are as opposed to where they ought to be,” there exist no such entities as “standard” radiation treatment volumes, “standard” portal design, or “standard” field sizes. Surgical and imaging series using CT, MRI, and Lymphangiogram (LAG) have revealed that fields of these sizes can easily miss the primary tumor and its extensions and the regional lymphatics at risk, and design of the pelvic fields needs to be done with care and use of confirmatory imaging (230,232–238). Plain films do not visualize the important soft tissues such as the cervical tumor and its extensions, the uterus, or the lymph nodes at risk. Additionally, bladder and rectal contrast and a vaginal obturator or cervical markers have been used to guide field design but are not sufficient (234,239). As with the brachytherapy component of treatment, the adequacy of the external beam fields and margins has a direct relationship with local and regional control (233). What may be considered a mysterious failure following definitive irradiation, perhaps caused by

“radiation resistance,” may actually be the result of a marginal miss due to external beam field design. Placement of radiation fields must take into account the alteration of the spatial relationship between the tumor and normal anatomy due to individual anatomic, tumor-induced, or treatment-related positional variations of the uterus and cervix, as well as knowledge of the location of the regional lymphatics (234,236). Radiation oncologists must be aware of these patterns of disease spread as well as have an in-depth understanding of CT anatomy when designing radiation fields following CT simulation. Identification and contouring of enlarged nodes in nodal regions at risk, as well as identification of the iliac vessels, which serve as surrogates for the location of unenlarged lymph nodes, are important in subsequently defining radiation field borders (Fig. 12.51). Additionally, contouring of the entire uterus and portions of the vagina will also ensure that these tissues are included in the radiation fields (Fig. 12.51). Reliance on bony anatomy alone for radiation field design rather than on CT-defined targets is discouraged. Generally, the superior border of the pelvic fields is at the S1–L5 interspace for early-stage disease (i.e., nonbulky IB or IIA) or at the L4–5 interspace for more advanced disease. The latter is used if one wants to cover the common iliac lymph nodes. Interestingly, Greer et al. evaluated “standard” pelvic fields (Anterior–Posterior [AP] - Posterior–Anterior [PA], 15 × 15 cm; lateral, 8 to 9 cm wide) for the treatment of cervical cancer in relationship to intraoperative findings. Based on intraoperative measurements of the location of the aortic bifurcation and the bifurcation of the common iliac arteries relative to the lumbosacral prominence (the anterior caudal border of L5), Greer et al. concluded that anterior and posterior treatment fields with a superior border at the L4–5 interspace are required to cover the internal iliac, external iliac, and obturator nodes as the bifurcations of the common iliac arteries were above the lumbosacral prominence in 87% of the patients studied. Coverage of the common iliacs could require extending the upper field border to the L3–4 interspace or even the L2–3 interspace in some patients (240). In a later series, Greer et al. treated 38 patients with cervical carcinoma with these expanded fields (AP–PA fields: median length and width of 20 and 17.5 cm; lateral fields: median width of 16.5 cm, posterior border including the entire sacrum), with an acceptable late actuarial severe complication rate of 14.8% (239). Obviously, with CT-based dosimetry, it is imperative to outline the vessels and/or nodes in these areas to determine the appropriate field borders as unnecessary irradiation of bowel could occur if all patients were treated to the L2–3 interspace based on this assumption (Fig. 12.51). CT is an excellent tool to either identify pathologically enlarged nodes, multiple small lymph nodes that by increased number rather than size are suspicious, or in the absence of nodes, the aortic and iliac bifurcations and the iliac vessels (228,230). Finlay et al., using CT-based planning, found that 79% of patients treated with conventional fields had inadequate coverage. For adequate coverage, the superior border may need to be as high as L3–4 to cover the common iliac nodes. Using CT-based planning, Finlay et al. reported that 95.4% of the patients who had “conventional” pelvic fields had inadequate coverage of nodes when these were contoured on treatment planning CT scans (241). The inferior border of the pelvic field is usually at the bottom of the ischial tuberosities or 3 to 4 cm below the most distal vaginal component of disease. Inguinal nodes are included if there is distal vaginal spread, in which case treatment of the vaginal introitus with margin would also be required. MRI is especially helpful in imaging vaginal tumor extension (234). The lateral borders of the AP–PA fields are important to design carefully as the 1.5- to 2.0-cm margin from the pelvic brim standardly recommended may be too narrow. Using lymphangiography, Pendlebury et al. found that in order to cover the lymphatic channels in the pelvis in 90% of cases, the lateral margins of the AP–PA fields would need to be 2.5 cm lateral to the pelvic brim

FIGURE 12.49. Brachytherapy plan for a patient with medically inoperable endometrial cancer in **A**: coronal, **B**: sagittal, and **C**: axial dimensions. Note dual tandems on the coronal image **A**.

(range of medial margins to cover lymph nodes, 0.5 to 3.0 cm) (231), and Bonin et al. found a margin of 2.6 cm (229). Intraoperative measurements have confirmed these findings (240). The lateral fields are even more prone to marginal misses than the AP-PA fields, as demonstrated in multiple series that have compared the standard textbook lateral fields (8 to 12 cm wide) to fields designed based on CT and MRI images (Fig. 12.52) (230,232,233,235–237,242). For the lateral fields, a commonly employed guideline is to place the posterior border in a
